Side view showing action of stoker.

In order that there shall be no damage to the revolving blades which have a speed of about 270 revolutions per minute, in case of some obstacle such as a large lump of coal getting into the stoker, a safety feature is incorporated. The blades are held in their radial positin by the centrifugal force due to the speed of revolution only. In case of a solid obstacle to their progress being met, the blades simply swing back on their pivots, thus saving the possibility of a broken blade, and stoppage of the stoker.

There are usually two hoppers to each furnace which practically divides the stoker into two units. This feature is very useful when cleaning fires, as it enables this operation to be performed with speed and ease. The usual plan which has been found best, is to disengage the feed latch on the side. This immediately stops the supply of fuel to one side of the grates, and this side automatically burns down. At the same

time a little fuel is placed on the dead plate, and as soon as this is ignited, the burnt down side can be dumped, the live coal pushed onto the bars, and the feed latch replaced. This is all that is necessary and the process is then repeated for the other side. It is claimed that the entire operation can be performed in four minutes.

An Interesting Installation

Our readers will remember in the Nov. 5th, 1920, issue of "Power House," there was a description of the plant of a flour mill, which had as a by-product the manufacture of salt. The plant alluded to is the Western Canada Flour Mills and at the time of writing the article the boilers were equipped with dumping bars. There are in this plant five Heine boilers and one B & W boiler, as can be seen in the illustration. These boilers have since the article was written been equipped with the Canada stoker, with very good results. The boilers under hand-firing conditions had to be run all the time in order to supply the demand for steam. With the stokers, and their greater capacity and flexibility it has been found possible to use a cheaper quality of coal, and to shut down two boilers for ordinary running.

This is a case where the units were of small size, three of the Heine boilers being of only 100 h. p., two others being of 125 h. p., while the B & W boiler is 306 h. p.

It can be readily seen that to instal, either an underfeed, chain grate or overfeed type of stoker would have entailed structural alterations of the boiler settings which would have made the cost of installation extremely high, and apart from the cost, the location of the boilers was such that the installation of any of these types would have been difficult.

A stoker of the nature of these fitted lends itself particularly to a job of this kind. This installation is a good illustration of finding the particular type of stoker to suit the local conditions. There are other conditions which would call for a different type, but the main point is that nowadays owing to the enterprise of stoker manufacturers, there is practically a type of stoker for every condition that arises and that can be installed at a first cost which makes it a profitable investment, whether the plant be of the order of 50,000 h. p. or 200 h. p.

HARVEST PLANT

(Continued from Page 23)

greater or less draft as dictated by the furnace condition itself.

As was mentioned previously, ash and other furnace residue as discharged by the stoker grates is collected in the ash pits which are accessible from the basement. The capacity of these ash pits are sufficient for at least 24 hours normal run, so that once daily suffices for their removal. They are removed in a small dump car propelled by hand and dumped into the skip hoist bucket. The distance from the ash pits to the skip hoist dump is approximately 30 ft. The skip hoist elevates the ashes 50 ft. and discharges them into a chute which in turn discharges into the concrete ash hopper. The skip bucket has a capacity of 1 cu. yd. of ashes and is operated by an electric hoist driven by a 7½ h. p. motor.

This equipment functions as a single cycle skip, starting from the bottom it travels to the upper position, stops, and after a time interval comes down to its original position and remains in this position until such time as the operator requires to start it.

The ash hopper, situated on the south side of the power house is of reinforced concrete. It has a capacity of about 75 cu. yds., is elevated above the railroad track and can be emptied either direct into the cars or dump wagons as occasion may demand. A portable chute has been provided to enable dump wagons to draw along side and receive their loads.

As the ashes when delivered to the hopper contain considerable moisture, heat has been provided within the hopper to be used during the winter to prevent the ashes from freezing.

The outstanding and perhaps somewhat unusual feature of this work is the manner in which it has been executed. From its inception to its completion the job has been handled by the company's own engineering and construction department and it is a concrete example of the self sustaining qualities of a modern industrial plant.

STOKER MANUFACTURERS' ASSOCIATION

Organized August 1, 1918

AN ASSOCIATION formed for the following objects:

The discussion of subjects of interest and value to the industry in which its members are engaged.

The advancement and improvement of that industry.

The standardization of manufacture and application.

The promotion of a spirit of co-operation among its members for the improved production and increased application of stokers.

The association aims to elevate the stoker industry to a high plane, its purpose being both ethical and practical.

A reputation for honest product, honorable business dealings and service to the public is a pre-requisite for membership in the Association. The emblem of the Association may therefore be regarded as an assurance of satisfactory business dealings with any member entitled to use it.

Membership.

American Engineering Company, Philadelphia, Pa.; Babcock & Wilcox Company, New York City; Burke Furnace Company, Chicago, Ill.; Combustion Engineering Corporation, New York City; Detroit Stoker Company, Detroit, Mich.; Green Engineering Company, East Chicago, Ind.; Illinois Stoker Company, Alton, Ill.; James A. Brady Foundry Company, Chicago, Ill.; Joseph H. Roach & Company, Inc., Philadelphia, Pa.; Laclede Christy Company, St. Louis, Mo.; Murphy Iron Works, Detroit, Mich.; Sanford Riley Stoker Company, Worcester, Mass.; Underfeed Stoker Company of America, Detroit, Mich.; Westinghouse Electric & Mfg. Company, East Pittsburgh, Pa. Joseph G. Worker, secretary, Stoker Manufacturers' Association, Eau Claire, Wisconsin.

Annual Meeting Date.

The Executive Committee have decided to hold the Annual Meeting at the Griswold Hotel, Eastern Point, New London, Conn., June 19, 20 and 21.

Make your reservation direct. This is a wonderful place. There will be boating, bathing, golf, dancing, side-trips, etc., so do not fail to make arrangements to be there. The New York Booking Office for the Griswold Hotel will be opened at the Hotel Biltmore, New York City, about April 15th so that members will be able to get accommodations by writing to this address about June 18th, which is just the time that we will have our meeting there.

A REMOTE IRON FOUNDRY

The island of South Georgia, where Sir Ernest Shackleton has been buried, is 2,000 miles from civilisation; but it is shortly to possess a complete, though small, iron foundry. A British firm has despatched to this distant isle one of its special comprehensive plants for making castings required in repairing the machinery of whaling vessels. Any necessary repairs to the ships can also becarried out by this equipment.

CLEANING OILY MACHINE PARTS

One of the most troublesome of the minor problems in the repair and overhauling of motor cars and other machinery is the perfect cleaning of parts which have been thoroughly soaked in oil. This problem is very ingeniously handled in the new central repair works in connection with London's great motor omnibus service. The parts to be cleaned are placed on wire trays mounted on a conveyor which moves very slowly through a cylindrical casing inside which are mounted on a number of pipes perforated with holes ⅛ of an inch in diameter. Hot caustic solution is forced through the pipes by a pump, and the multitude of jets reach every part of the gear wheels and other portions of machinery passing through. When the parts emerge from the cylinder they are practically free from oil. In this way a process which generally is most prolonged and laborious is perfectly carried out in a minute or two.

Mill scale and adverse weather conditions promote corrosion of steel. Mill scale and all rust must be removed before any paint is designed to protect the clean steel surface. The second coat of paint protects the first coat from the weather and this second coat must, therefore, be impervious to moisture and frost.

Hand Operated Stokers For The Small Unit

The Stoker Described and Illustrated in This Article Has Been Installed in a Number of Canadian Industrial Plants—It Can be Equipped With Mechanical Feed if Conditions Require it

AN NTERESTING example of the type of stoker that may be termed semi-automatic, in that it is intended for hand operation of the grates themselves, is the Files Stoker which is made in Canada by the Waterous Engine Co., Brantford.

The stoker is designed to get away from the disadvantages attendant on hand firing and cleaning, and at the same time be adaptable for small units. It is easily attached to any boiler, the only work to be done on the boiler fronts being the drilling of a few holes to support the lever brackets, which are set at the front of the boiler.

Stoker Operation

The grate is inclined to the back of the boiler, and the coal which is fed onto the front bars, is there coked, the volatile gases passing over the incandescent fuel bed, where complete combustion takes place. The coked coal is gradually worked down the inclined surface by the operation of the stoker bar handles, which are situated at the boiler front. The operation of the handles turn the stoker's bars up into the fire about six inches, breaking up the clinker and ash, and pushing it forward to the cleaning plate, while the coked fuel is also advanced along the inclined bars. There is thus a free passage for air through the fuel bed constantly maintained.

The cleaning plate at the lower end of the grate is counterbalanced, and a single pull on the lever is sufficient to dump the ash and clinker into the ashpit, without the loss of any unburned coal, and with absolutely no waste of time, therefore no drop in pressure.

The illustration of the operation of the stoker gives a very clear idea of the processes. Figure 1 shows the normal condition of the fire, the depth of fuel bed being governed by the quality of coal being burned. In this picture the grates are all flat and the dumping or cleaning plate closed.

In the next figure the dumping grate has been opened and the clinker and ash resting on it dropped into the ashpit. The shape of structure of this ashpit is a question of local conditions. There is no restriction as far as the stoker is concerned to any particular style of ashpit.

Figure 3 shows the lower section of the stoker bars raised up, throwing the back portion of the fire which is practically all consumed, and the ash and clinker resting on the lower part of the bars, onto the dump plate, ready for the operation as shown in Figure 2.

Figure 4 shows the front section of the fire bars lifted, and moving the freshly coked coal from the front of the grate onto the back part which has just been cleaned. Fresh coal will be then placed on to the front bar, ready for coking.

This front grate bar is made with specially large air spaces, to develop quick ignition when burning high volatile fuel. In some cases it is necessary to fit an ignition arch at the front of the furnace for the same reason. These are modifications to suit different kinds of coal, and make no difference to the general construction of the stoker. A stoker of this kind is easily installed on any existing type of boiler, without alteration to the settings, and with a very slight loss of time. Indeed, it is claimed that they can be installed over a week end. High boiler ratings can be achieved when desired, and maintained for fairly long periods.

Burning Canadian Lignite on Chain Grates

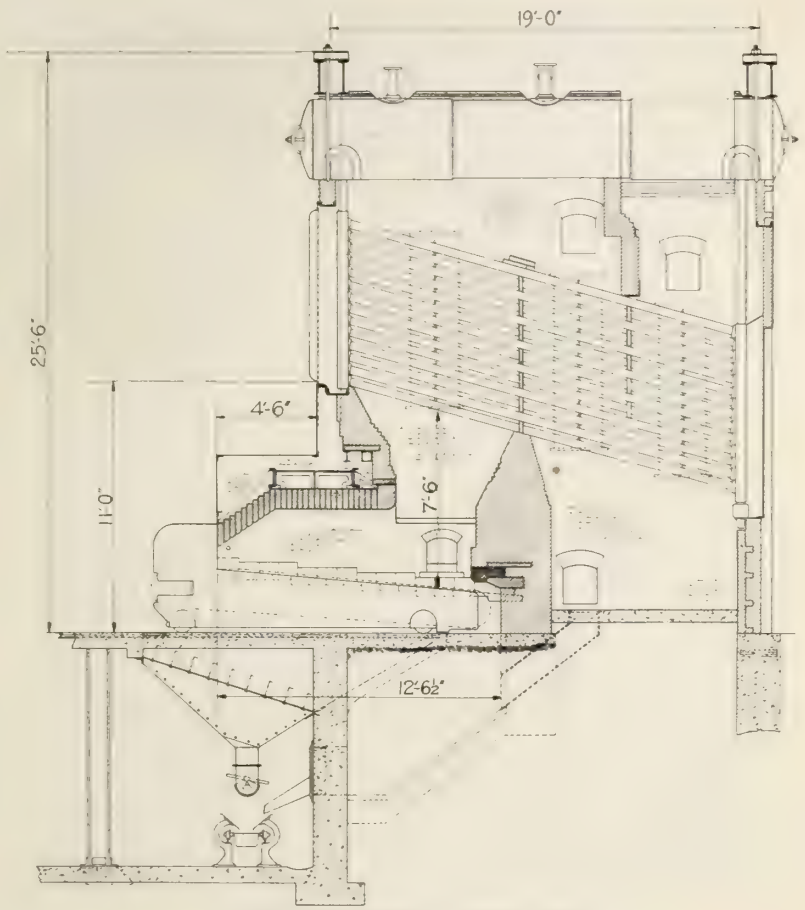
There Are a Number of Installations in Saskatchewan and Manitoba Enabling These Rich Deposits to be Put to Practical Use—A Typical Furnace Arrangement is Described

THE LIGNITE fields of Saskatchewan and Manitoba are rapidly growing in importance as sources of fuel for these and parts of the adjoining provinces. Some idea of the extent of the deposits may be gained from the statement that has been made that at one point on the C. P. R. lines there is a bed of lignite that is actually several hundred feet thick. More effective utilization of the potential natural wealth represented by these deposits has of recent years commanded the very serious attention of the provincial and even the Dominion governments. Among the plans considered are carbonization, briquetting and various combinations of these two processes involving the recovery of valuable by-products. Developments of this nature will undoubtedly be of large importance in the industrial growth of Canada, but the full benefit of this work cannot well accrue for many years. The most pressing need of the moment is an increased use of raw lignite for the production of power and heat to reduce the costly importation of higher grade fuels from other provinces and to assist in lowering the cost of power as a stimulus to greater industrial development.

Several chain grate stoker installations recently made in this district have an important bearing on this matter since the results secured have been highly satisfactory. The lignite burned in many of these plants comes from the well-known Souris fields, and a general discussion of the problems to be met when using this fuel may be of interest.

A typical approximate analysis of Souris lignite follows:

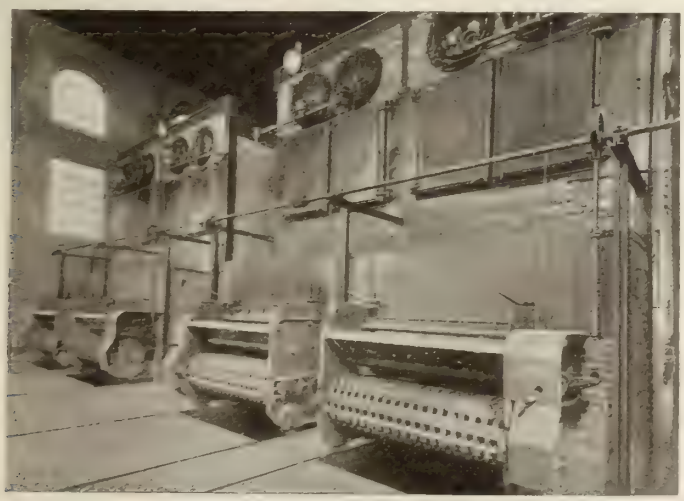
Moisture 31.66 per cent.
Volatile 25.25 per cent.
Fixed Carbon 37.05 per cent.
Ash 6.04 per cent.
B. t. u. 7800.



Laclede-Christy Stoker for burning lignite.

This fuel has all the well-known characteristics of lignite—high moisture, low heat value and pronounced woody structure. It is quite apparent that to obtain high boiler capacities when burning this material it is necessary not only to provide larger grate surface than is required with bituminous coal, but also to pay particular attention to the furnace design and arch placement. Lignite, because of its high moisture content, lights up very reluctantly and since it is obvious that fuel can be burned only as fast as it can be ignited, it is imperative that the furnace, bridge wall and arch layout be such as to induce very high ignition temperatures. This result can best be brought about by providing a high boiler setting, a bridge wall with a high vertical face to reflect heat forward toward the feed gate and a long, high arch to direct the heat full on the incoming coal.

Such a furnace arrangement is shown in the cut of a light line drawing of a typical boiler and stoker layout. It will be noted that there is ample furnace volume and long gas travel before the entrance to the tube bank, which condition makes for complete combustion of the gases arising from the grate. Another matter of note is the provision for high fuel bed temperatures without any suggestion of "bottling the furnace" or restricting the gas exit. These high fuel



Front view of stokers.

bed temperatures are of first importance in inducing high chemical activity of the fuel bed, and hence high rates of burning. This is particularly necessary with lignite because not only does this fuel tend to smolder and glow rather than burn briskly, but to make matters worse the high moisture content very effectively limits furnace temperatures to relatively low values.

The physical condition of the fuel itself deserves more than a passing word. In general the best size for use on chain grate stokers is slack or screenings which will pass through a 1¼-in. or a 1½-in. screen and it is quite necessary that there be a considerable quantity of the so-called "fines" or small particles. Lignite of larger size than that described, or that containing little of the "fines," does not ignite readily and burns slowly and unevenly. While the design of the furnace is of prime importance in burning lignites, yet the matter of draft also demands serious attention. In common with other fuel burning problems it is advisable in these cases to have available a little more draft than the actual maximum requirements. A plant with excellent facilities for the production of good draft is in a much better situation than one in which the draft is limited. In general it may be said that it is advisable to provide between 4 and 5 in. draft over the fire.

These considerations show the importance of insuring the application of the best results are to be obtained. It is sign of a stoker and boiler layout for the utilization of Canadian lignites if the best results are to b eobtained. It is gratifying to know, however, that the application of these principles and practices do make possible high capacities and economies when burning this cheap, low grade fuel.

HAND OPERATED STOKERS

Continued on page 26

A grate of this type gives practically all the features of the purely mechanical stoker, without the heavy initial outlay, which is a big consideration in the small plant.

Mechanical Feed

By equipping the boiler with a mechanical feed system in conjunction with the stoker, and especially if the hopper of the mechanical feeder is fed by coal handling machinery, considerable saving in labor can be accomplished. Even where the hoppers must be filled by hand there is a saving due to the elimination of the opening and closing of fire doors, and the regularity of the feed possible by mechanical means.

This mechanical feed arrangement can be installed with slight trouble, as it bolts right on to the boiler front, and the standard setting is in no way interfered with.

BUREAU OF MINES PUBLICATION

The issue of Technical Paper 268, "Preparation and uses of tar and its simple crude derivatives," by W. W. Odell, fuel engineer, is announced by the United States Bureau of Mines.

The importance of tar as a commercial product has been emphasized during the past five or six years more than ever before, says the author. In that time, the market for tar and its products fluctuated in an unprecedented way, because of the war and other conditions, with the result that the production of tar and tar products increased greatly. A large proportion of the increase is due to the installation of by-product coke ovens, which are fast replacing the bee-hive ovens, from which tar and other by-products are not recovered. The increasing demand for steel and the shortage of anthracite coal during the war were a great impetus to the coking industry. In 1920 tar was being produced in greater quantities than ever before, but the entire output was not on the market for sale, as increasingly large quantities were being used for fuel. However, in some localities where the output of tar was small or was of inferior quality—particularly water-gas tar—there seemed to be no great demand for the product.

This paper discusses the uses to which some of the various tars are put and shows briefly the usual methods of working up tar into some of its simple or easily prepared derivatives, for which a market can generally be found. Although coal tars are given chief consideration, the properties and characteristics of water-gas tar are mentioned for the reason that this tar is often produced in plants where coal tar is made, the mixed tar being collected and marketed, and for the further reason that the presence of water-gas tar in some coal-tar products is specifically interdicted by commercial specifications. This publication is not a handbook on tar distillation, for that subject can hardly be covered adequately in such limited space, but is published by the Bureau of Mines as a general treatise on the utilization of tar.

Technical Paper 268 may be obtained by addressing the Bureau of Mines, Washington, D. C.

FUSE BULLETIN

The thoroughly vented renewable fuse, recently developed by Westinghouse engineers, is discussed and illustrated in Folder 4,472, entitled "Shurvent Protection," which has just been published by the Westinghouse Electric & Manufacturing Company, East Pittsburg, Pa.

The folder explains the application and design of fuses for the protection of low-voltage circuits up to 600 volts for both alternating-current and direct-current.

Every part of the Shurvent fuse is described in this folder and pen-and-ink sketches are used to show how the renewal of both the ferrule and knife-blade types of fuses is accomplised. Although Shurvent Renewable Fuses are featured in this publication, various other subjects are covered, such as the conditions which must be met to obtain the underwriters' approval, style numbers, weights, prices and other tabulated data.

The Renfrew Creamery is having its present refrigeration capacity doubled owing to the increase in cream business. The Linde Canadian Refrigeration Co., of Montreal, the same firm that installed the system is making the addition. During the year 1921, the creamery put out nearly a quarter of a million pounds of butter and 13,000 gallons of ice cream. The staff has also been considerably increased.

Erection of four buildings at a cost of $1,500,000 is contained in a request made by the Toronto University to the Provincial Government. This program includes a new forestry and botany building, an administration building, additions to the heating plant and a woman's building.

Mr. C. Little of Robinson, Little Co., 343 Richmond St., London, Ont., plans to build an arena. The cost will be about $150,000. Prices wanted on artificial ice-making equipment.

The following figures show the receipts at the Port of Toronto, Ont., for the last three fiscal years. For the year 1919-20, $43,622,135. For the year 1920-21, $31,490,719. For the year 1921-22, $43,616,887.

Jones & Glassco Reg'd. of Montreal and Toronto, have been appointed the sole Canadian agents for the Unchokeable Pump Ltd. of London, Eng. The Unchokeable Pump is constructed on the centrifugal principle, but so designed that fibrous solids, skins, sacking, etc., will pass through it without difficulty.

AIR DRIVEN WIRE BRUSH

There has been placed on the market recently an air driven brush for which some remarkable results are claimed. The tool is especially adapted for removing paint, rust, dirt, and scale from tanks, cars, and structural steel forms, where the area to be cleaned is large and fast work is required. The speed at which the brush rotates is an interesting feature. Its free speed is 4,200 r.p.m. when 90 lbs. of air is supplied the three cylinder motor. The speed, it is claimed, not only permits of faster working but actually adds life to the brush. Light weight is obtained by using an aluminum casing reinforced with cast-in steel bushings. The complete machine weighs only 14 pounds. The diameter of the brush is 6 in. and the length of the tool over-all is 17-1/2 in. It is claimed that on a prolonged test of the brush, steel gondola cars averaging 540 sq. ft. of surface were cleaned in 3½ hours. Rust and old paint were removed in each instance. The tool is being marketed by the Ingersoll-Rand Co. of New York, and under the trade name of "Little David."

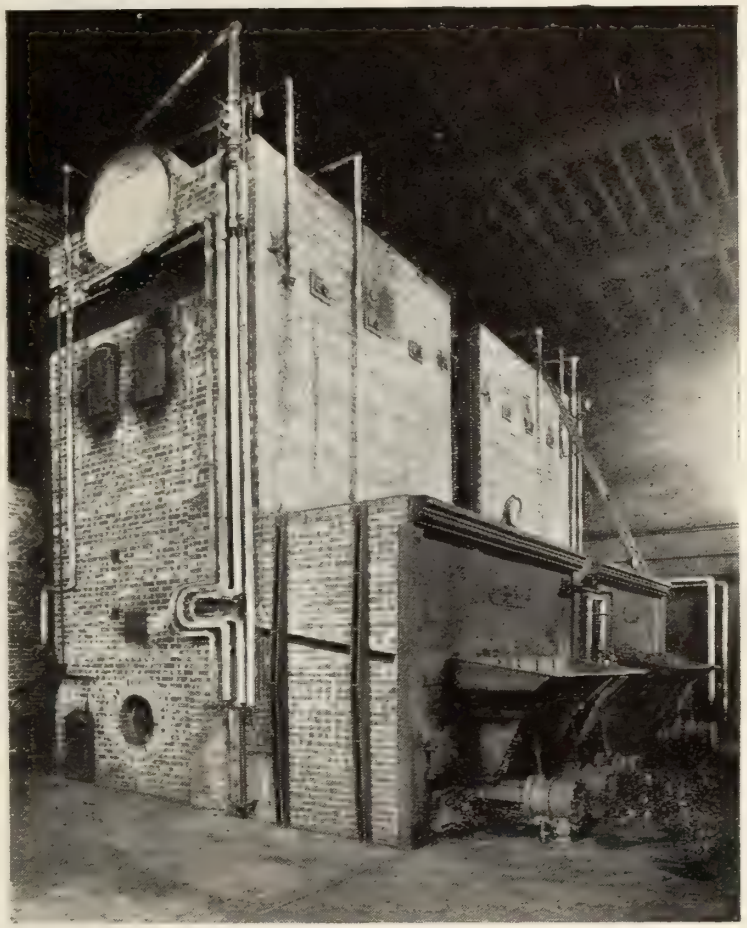
Erie City Boilers and MacLean Stokers

This is the Combination Used in the Plant of the Canadian Dyer's Association, Toronto—The Boilers Are of Water Tube, and the Stokers of the Underfeed Type

THERE is one type of industry which is insistent in its demands for steam in large quantities at uncertain periods, much in the same manner as a central station. We refer to the textile plant, and more particularly to the dyeing industry. This kind of work calls for hot water and steam at almost every step, and the men in charge of the processes have no thought but to get the required heat in the water or the drying apparatus in the least possible time.

This kind of work demands boiler equipment that can rise to the occasion and an interesting installation is to be found in the plant of the Canadian Dyers Association, Toronto. The processes cover the rough or undyed cloth coming from the mills, to the finished article ready for making up.

The cloth as it comes in from the mill is of creamy color, and is far from being in the smooth state that is familiar in the made up goods. In order to produce this appearance it is rolled in special rollers and passed through machines which thoroughly scour it, removing any dirt that may have been picked up. It is then ready to go to the dyeing kettles. There are a large number of these kettles, and then there are the dryers. Altogether the demand for hot water reaches about 400,000 gallons per day. The steam required for drying purposes is furnished at about 80 lbs. pressure, the temperature in the drying room being about 180 degrees.



MacLean Stokers on Erie City Boilers.

The Steam Equipment

The steam generating equipment consists of two Erie City boilers of 400 h. p. each. They are fitted with three retort underfeed stokers made by the MacLean Underfeed Stoker Co., Toronto. These stokers have some interesting features, the chief points being in the method of steam distribution to the ram and the form of tuyeres used in the grates.

Showing Front of Boilers, Hoppers and Stoker Cylinders.

The general arrangement of the stoker is of the usual underfeed type with a ram operated by steam, pushing the coal into the bottom of a trough, underneath the burning fuel. This process causes the gases in the fuel to be first distilled and ignited as they pass through the burning top layer of fuel, and after the gases are set free the remaining carbon is pushed up to the top of the fire, the ash and clinker being pushed over onto the side plates where they can be taken away at cleaning time.

In the underfeed type of stoker forced draft is a necessity, and the air is admitted to the fire through tuyeres placed at the side of the fuel trough. One of the feature of the MacLean stoker is the construction of these tuyeres. The portion which is most susceptible to burning is made separate, but easily fitted into the main body of the tuyere. It can thus be easily renewed, and it is also made in such a manner that the projections which guide the renewable

Enlarged View of Timing Mechanism.

portion into the base, also serve as a preventive of coal siftings dropping into the air chamber. The method of distributing the steam to the ram cylinders is one developed by the MacLean Underfeed Stoker, and differs from the method employed in other underfeed types quite considerably. The following description with the illustrations will make it clear.

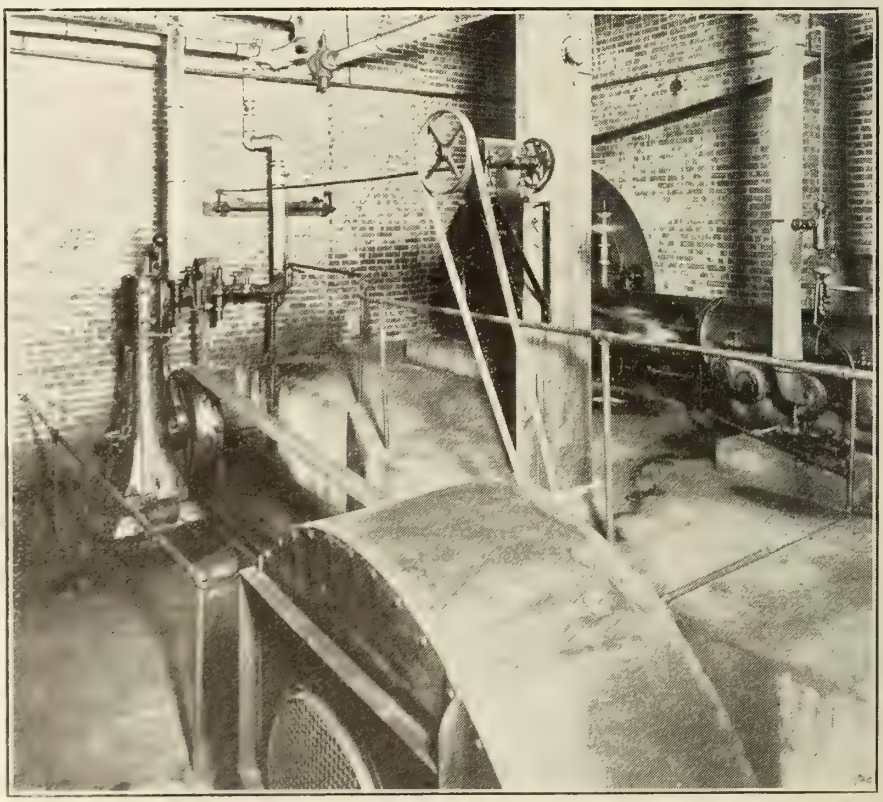
Automatic Control

The automatic feed controlling system of the MacLean Underfeed Stoker is a positive yet simple means of governing the amount of coal delivered by the stoker to the furnace and the quantity of air supplied by the blower. It enables the operator to easily adjust and correctly proportion these to suit the class of coal used, and the demands for steam upon the boilers, so as to automatically maintain a constant uniform steam pressure under all conditions of

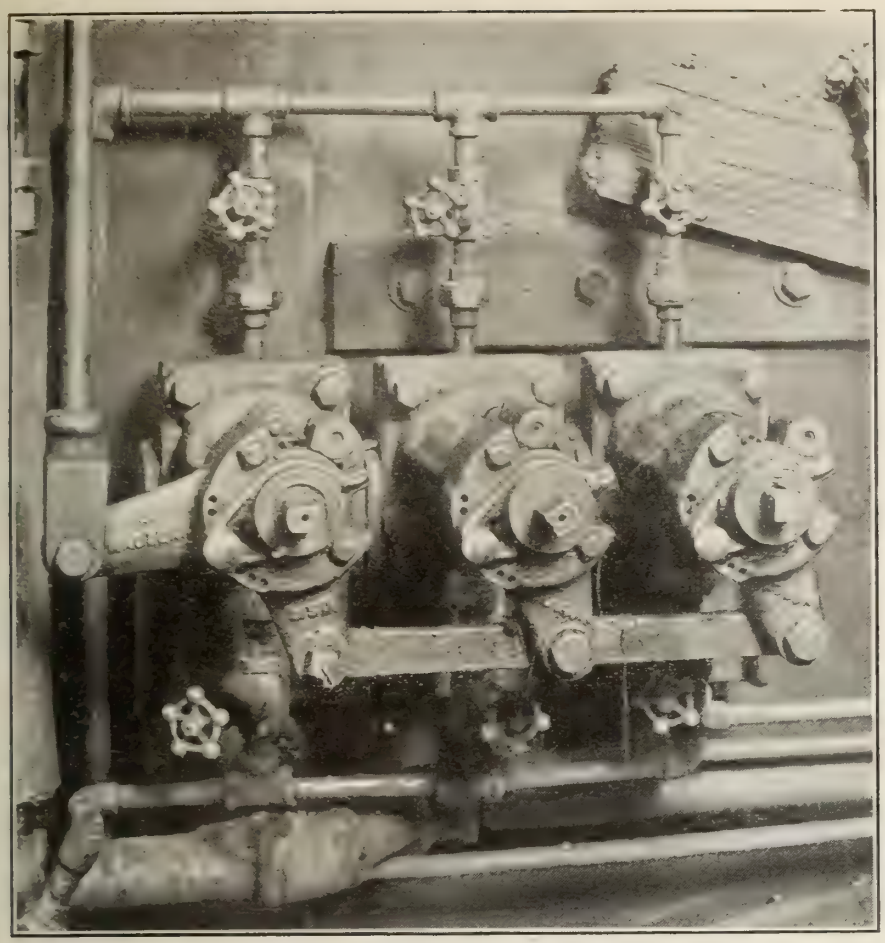
The speed of the steam engine or electric motor driving the blower is controlled by a steam pressure regulator which is set for any desired boiler pressure and is governed by the rise and fall of the pressure itself. Any variation in the speed of the blower is imparted to a reduction gear through a belt drive from a small pulley on the blower shaft, the oscillating motion set up by the reduction gear is carried by connecting rods to an adjustable ratchet operated timing valve which may be located on the boiler front or placed in any other convenient position in the boiler room. From the timing valve a small pipe leads to the main valve steam chest on the stoker cylinder. Fluid pressure is conveyed through this pipe with each rotation of the timing valve and actuates the main valve of the stoker which in turn controls the number of strokes of the piston operated ram and consequently the quantity of coal fed to the furnace.

Following the operation of the automatic control it will be seen that should the boiler pressure fall slightly below the desired point, the steam pressure regulator acts on the motive power driving the blower, increasing its speed, which thus delivers more air to the furnace for combustion. At the same time the speed of the reduction gear is increased, being driven by the blower. This increases the rate of the operation of the timing valve, which in turn controls the speed of the stoker ram and the delivery of coal to the furnace. It will thus be apparent that as the boiler pressure falls the rate of combustion is increased which immediately raises the boiler pressure again.

If the boiler pressure should rise above the desired point the steam pressure regulator will reduce the speed of the blower and the reverse of the above described operations will occur, resulting in the lowering of the rate of combustion in the furnace and the consequent falling of the boiler pressure. The



Fan Engine, Fan, and Stoker Control.



Timing Arrangement

variations of rise and fall of the boiler pressure necessary to alter the rate of the coal feed and air supply are so slight that the result is a practically continuous even steam pressure.

Varying conditions of boiler loads and grades of coal used are easily taken care of. The adjustable ratchet permits the increasing or decreasing of the amount of coal fed through the stoker over a wide range, by setting the index lever so that the pawls take a greater or lesser number of teeth on the ratchet wheel at every oscillation. With this adjustment it is possible to vary the amount of coal without altering the speed of the blower and thus the ratio of coal to air can be proportioned to give efficient combustion. The index lever has eight positions of adjustment, also a zero position stopping the coal feed altogether. The timing valve may also be rotated by a small hand crank and in this way the stoker made to feed any desired number of charges of coal independently of the automatic operation. The design of the timing valve is such that a number of these may be operated together as a set by a single drive without interfering with the provision made for the individual control of the coal feed to each retort. This feature is of great advantage where several retorts are installed in the same furnace or under boilers of different sizes.

The main valve steam chest is cast integrally with the stoker cylinder and the main valve itself which is completely blanked off within the steam chest, operates close up to the cylinder bore making the ports for the admission of steam to the piston very short and direct, thereby reducing the cylinder clearance displacement to a minimum.

The arrangement, it will be seen, tends to great flexibility. The method of controlling the steam supply to the cylinders reduces clearance losses to a minimum, and also simplifies the mechanical parts necessary for operation.

BRITISH ELECTRICAL RESEARCH

Practically every loading section of industry in Great Britain has its organised co-operative research Association. In the case of brass, copper, and other metals not containing iron a great deal of very interesting research is now being carried on. The casting of brass, influence of impurities on the working of copper, the electric melting of non-ferreous metals, and the grinding, jointing, and polishing of such metals are being closely studied. Perhaps the most important part of this research lies in the investigation of corrosion. The production of rustless iron and steel has stimulated the brass and other industries to give attention to the causes of corrosion. It is stated that the examination of tarnishing, which is the first stage towards corrosion, has already yielded very interesting results.

WELDING BY CLOCKWORK

In shipbuilding and in many engineering operations, it is necessary to fix brass studs and other small parts to iron plates. This operation is usually performed by drilling holes in the plate, each hole being drilled separately. By means of an ingenious invention recently perfected by a British firm, the process is carried out in a few seconds by electric welding. The working of the machine is almost entirely automatic from the moment the stud is placed in position. Each size of stud requires a different time for welding it to the plate, and the machine can be set to give exactly the period required to make a perfect weld. The tests which have been made proved that the machine is able to weld 120 brass studs within an hour. It might be thought that welding does not give such a firm arrangement as screwing the stud into a hole in the plate, but when the welded stud is hammered the brass will break before the weld yields. Another advantage of the machine is that work can be satisfactorily carried out by semi-skilled labor.—*100-ton Booster.*

NEW SHAFT COUPLING

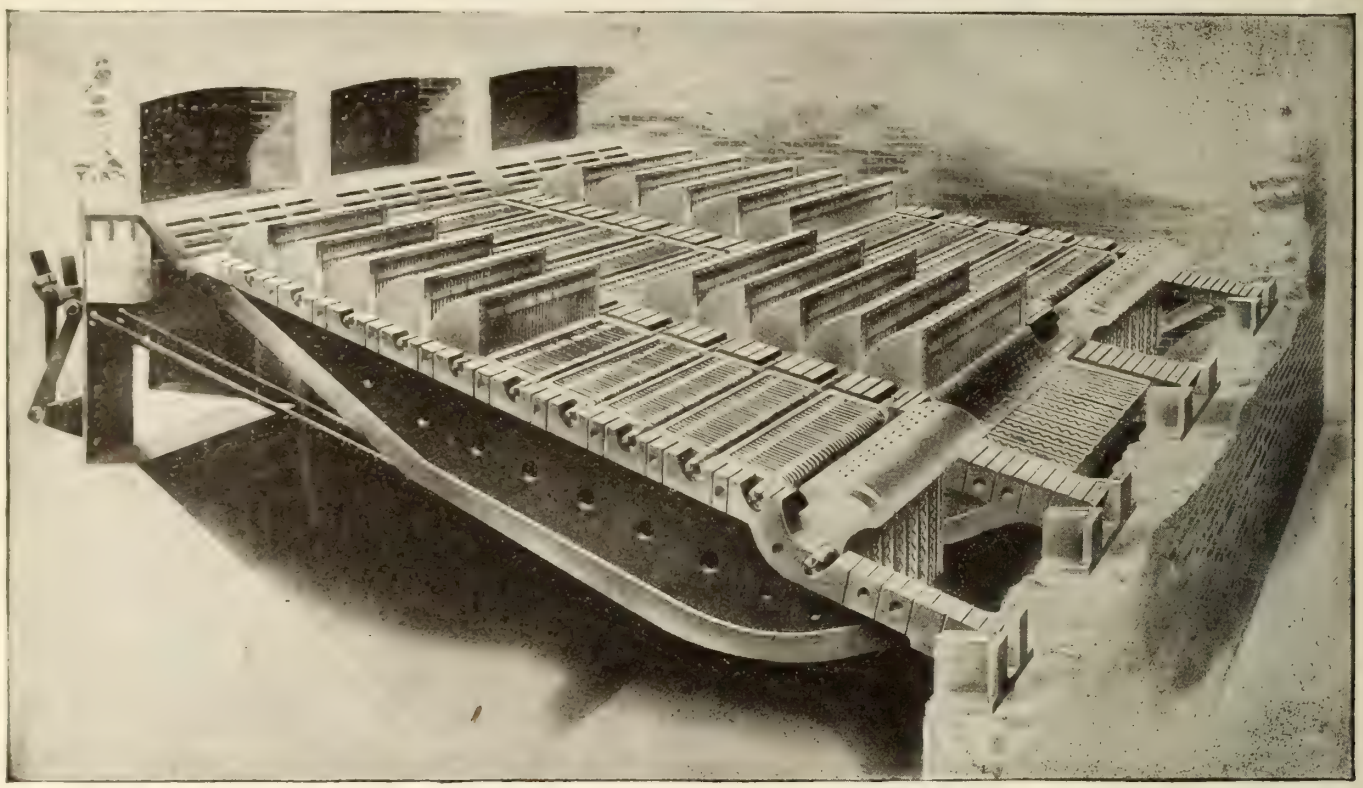
An ingenious method of coupling shafts for power transmission has recently been devised by the Coventry Chain Co. of Coventry, England. It comprises a double chain, i.e., two chains side by side, which passes round toothed flanges on shafts which it is desired to couple. The coupling is readily made by a bolt passing through adjacent links connecting up the two ends of the chain in the usual way. The coupling has a very high factor of safety, it is perfectly balanced, being machined all over, and does not require any lubrication.

The facility for disconnecting the shafts will be apparent, and the method gives a large number of possible adjustments by which one shaft may be angularly set relative to the other through the medium of the teeth into which the rollers of the chain are fitted. Although this coupling is not designed to replace universal joints it is obvious that a measure of flexibility is obtained, and it is stated that the coupling can be used to couple shafts with a deviation in angular movements of two degrees.

Relative end movement between the two shafts is also provided for, limited to about 1-16th of the shaft diameter. A special application of this chain coupling is with regard to automobiles, particularly in such cases as that of the magneto shaft where angular adjustment is sometimes required and where a slight flexibility is considered advantageous to avoid transmission of small vibrations. The coupling is manufactured in fifteen sizes which have been completely standardized, the largest type being capable of transmitting 180 h.p. at 100 revolutions per minute.

Files Stokers

Hand Operated



Simplicity—Ruggedness—Effectiveness—outstanding features of Files Stokers

DUE to the absence of complicated and intricate parts, the average fireman is well able to operate the stoker with maximum efficiency—expert or expensive labor is unnecessary.

Clinker is ground out, ash and refuse removed, coal distributed—the fire is kept clean, uniform, rich—all by the easy, simple movement of the pull-rods at the boiler front. Not once are the fire doors opened to perform any of these operations. Cool air—that destroys draft, chills heated surfaces and strains the boiler—is eliminated.

Consult the perspective view of the stoker. It illustrates the distinctive movement of the stoker bars and the method of removing refuse by means of the counter-balanced cleaning plate. There is no drop in steam pressure nor is live coke lost into the ashpit during these operations.

Perforations and corrugations throughout the various stoker parts provide constant circulation and proper distribution of air (absolute necessities for efficient combustion), and prevent warping or burning of these parts. Ample provision is made for expansion.

Combustion is complete at all times; maximum evaporation is guaranteed; overloads carried for long intervals are a natural requirement easily met by the stokers.

The entire stoker is designed simply but ruggedly; to insure continuous service with smallest operating and maintenance costs. Numerous plants—large and small—are benefiting from these exclusive features of Files Stokers.

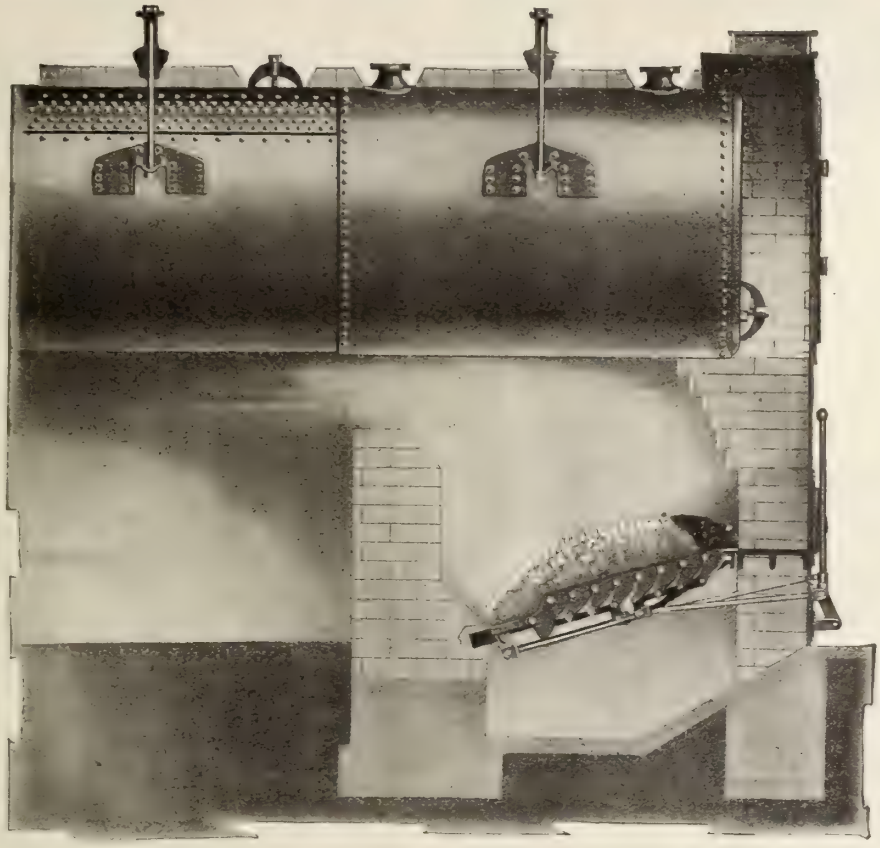
FILES HAND STOKERS



Over 500,000 Horse Power of Files Stokers in Operation

INSTALLATION—

The Files Hand Stokers can be easily installed in a few days. The boiler setting is not disturbed in any way except the deepening of the ash pit to accommodate the slope of the stoker. No alterations to boiler fronts are necessary other than drilling of holes for operating levers.

FUEL—

Aside from burning all grades of bituminous coal, heavy mixtures of anthracite or screenings mixed with bituminous coal or mixtures of coke and similar fuels can be used with excellent results with Files Hand Stokers.

The Files Stoker is not only applicable to all types and sizes of boilers, but extends its line of usefulness to all equipment burning coal for fuel, including furnaces, stills, ovens, etc. In each instance the high degree of combustion efficiency, that it maintains, is a source of great saving and profit to all who have installed it and invariably found it the most reasonable investment and the most effective equipment of its kind.

"Dad" Wickens Passes

AFTER A LIFE full of activity in his chosen profession, Albert M. Wickens, known by all his friends as "Dad" Wickens, passed away at his Toronto home on April 7th, at the ripe age of eighty.

In the year 1885 he moved to the city of Toronto and took the position of chief engineer for the Globe Printing Co., retaining it for seven years. During his term of service the premises were moved from their original location at the corner of what was then King St. E. and Victoria Lane to their present location, and this removing was performed without the loss of a single edition of their paper. This was largely due to the preparation and foresight of the chief engineer. In the new premises Mr. Wickens installed what was the first electric drive in Canada.

His next appointment was that of chief engineer of the Parliament Buildings in Queen's Park. Here again "Dad" was able to show his originality in the matter of electric fittings, a large number of which were made from his own patterns. He included in his duties at the Parliament Building the inspection of all boilers in the Provincial government buildings.

Resigning from the Government service, he was appointed chief engineer of the boiler department of the Canadian Casualty and Boiler Insurance Co., which later became the General Accident Insurance Co., which position he held until he retired about 1912. He was connected with the company up till two or three years ago as a special executive.

"Dad" Wickens was always very active in work for the betterment of the status of his fellow engineers. He was the founder of the Canadian Association of Stationary Engineers, and was active in its service almost continuously from its inception to the time of his last illness. He also organized the Ontario Association of Stationary Engineers, which society ceased to exist with the inauguration of the compulsory certificate, which was the object it had in view. He later was instrumental in organizing the United Craftsmen's Council in Toronto, and saw it grow until last year the first convention was held in Toronto, being attended by members from all over the U.S.A. and Canada.

Probably one of his most useful works was the part he played in bringing into existence and to ultimate success the Toronto Technical School, in collaboration with Major John A. Carlaw, the late Mr. J. A. Orr, and Mr. A. G. Horwood. "Dad" served continuously on the Technical School Board until it was absorbed by the Board of Education.

He was a member of the Masonic order, being connected with Rehoboam Lodge, and was also a member of the I.O.O.F. and was a Presbyterian.

He is survived by three daughters, and two sons, a brother also surviving him.

The Stoker Era

THIS MIGHT well be termed the era of mechanical stoking in power plants, the hand method of firing having been eliminated in all but the smallest plants, while in them it is possible to use a type of stoker which while not being entirely mechanical, yet fulfils the purpose to some extent. This issue of Power House contains a number of articles on typical stoker installations, most of the plants being of medium size, while the semi-mechanical stoker is represented also.

As in the case of the steam boiler, while it is divided into distinct types, there are a great number of makers of these types, each of whom lends some touch of individuality to the apparatus he manufactures. It is gratifying to know that there are a number of stokers manufactured in Canada, some of them being built by subsidiary companies of American firms, others being purely Canadian in their origin and direction. The application of mechanical stoking to Canadian industrial power plants is likewise getting wider every day.

There is practically a stoker for every type of plant, even the small one of one boiler being susceptible of improvement by the installation of some form of stoker or movable grate bar, which will tend to increase efficiency. In the very small plant this is the whole function of the stoker, as in the nature of the case it cannot well eliminate labor. In the larger installations, however, the stoker not only gives more efficient combustion, making a saving in fuel, but it also saves labor, making a direct saving of wages. It also offers the possibility of running boilers to high ratings, thus making a further reduction in fixed charges, both on the investment in the equipment, and in the amount of space to be allowed for power generation. When a factory or central station is situated in the high rental district of a large city this is again a consideration. When stokers are installed in conjunction with their natural complement, ash and coal conveying machinery the plant reaches its highest possible efficiency.

It must be borne in mind, that no matter what kind of machinery is installed, and how well it may be designed for the part it is to play, it will have but little chance of success unless it has the benefit of skilled and careful attention. It is a great mistake to assume that because a plant has been equipped with high priced automatic machinery, that the commonest kind of labor can be used to operate it. The machinery has eliminated just that kind of labor. The men who are still necessary for its operation should be the best available, and their compensation should be based on an appreciation of the value of the machinery in their charge.

Progress in New Equipment

A New Type of Multiple Underfeed Stoker

Many Advantages Are Claimed for the Stoker Described in the Following Article, and Curves of Both Calculated Performance and Actual Performance Are Given

By ROBERT JUNE

THE GENERATION of steam with coal as fuel has been practically revolutionized within the past few years. Boilers have been driven to capacities hardly dreamed of ten years ago. As a result, very much higher over-all efficiencies have been secured. The cost of production has been materially lowered, due to the lessened number of boilers required, and to economies effected in fuel saving, labor and maintenance.

This great difference has been due to the development of the underfeed stoker. The superiority of this type of stoker lies in its range of capacity, its complete mixing of air and fuel, and its provision for the removal of ash at regular intervals.

The multiple retort stoker is the stoker for large installations and exceedingly high ratings. Indeed, so completely has the forced draft stoker preempted this field that it is unusual to go into a large central station or high duty large-power plant of any sort built within recent years, and find any other types of stokers installed.

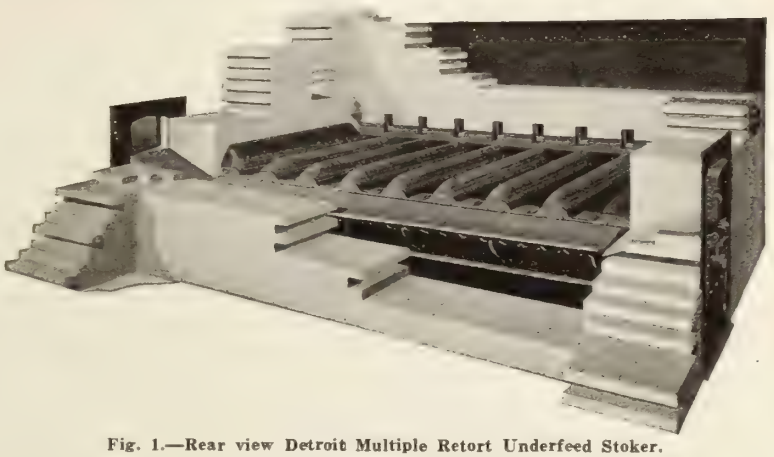

Fig. 1.—Rear view Detroit Multiple Retort Underfeed Stoker.

There are a number of reasons for this. First of all, the underfeed stoker is adapted to all grades of bituminous coal. Next, it is essentially a forced draft stoker, since it operates with restricted air openings, and very deep fires. The forcing capacity is almost unlimited, instances being known where this stoker has been driven to over 400 per cent. rating.

Fig. 2.—Front view Detroit Multiple Retort Underfeed Stoker.

Stoker Designed on New Principle

The design of the underfeed stoker provides for a driven ram, which forces the fresh coal into a large receiving retort, contained within the furnace, and from there up under the fuel bed. Designers of the earlier types of underfeed stokers considered it essential that the fuel bed should be inclined at an angle of 20 to 30 degrees, in order to facilitate the rearward movement of the fuel. The influence of the earlier designers in this particular respect has largely controlled stoker design until the present day, although the fact has long been recognized that a steeply inclined fuel bed possesses serious disadvantages. Such a fuel bed is irregular in structure and at times may contain large lumps of coke, or quantities of clinker, or of soft unattached coal. In pushing a fuel bed so composed down an incline, an irregularity of movement occurs, and slides are occasioned which roll large bodies of fuel on the dump plates. When such slides occur, very marked irregularities in the thickness of the fuel bed are caused, and

there is frequently a heavy fire on the dump plates, the net result being lowered combustion efficiency and ideal clinker forming conditions on the dump.

In order to overcome these disadvantages, the Detroit Stoker Company, Detroit, Michigan, has designed an entirely new type of underfeed stoker. This stoker is made in two designs, for boilers up to three or four hundred H. P. Over one hundred installations have been made of this stoker and all are operating successfully.

The larger stoker is of the multiple retort and cleaning type for large installations. This stoker is designed on principles which have been successfully worked out in the smaller machine. It has been thoroughly tried out for two years under all conditions of operation.

In describing the new stoker, we will deal first with the multiple retort type, (Fig. 1 and 2), and then describe briefly the modifications of this found in the smaller retort design.

Multiple Retort Stoker

To feed coal into one end of a furnace, to move it to the rear at such a rate, and under such control, that combustion is entirely completed within the furnace and only refuse reaches the dump, is in itslf an innovation. To do this in such a way that combustion is uniformly progressive throughout the entire length of the fuel bed, and to do it with fuels of different characteristics, is an accomplishment that marks a distinct step forward. It is this accomplishment which distinguishes the Detroit Multiple retort underfeed stoker. Adequate recognition has been taken in the design of the conditions existing in a moving fuel bed, and positive means provided for controlling these conditions. To accomplish this many old theories now in practice with underfeed stokers had to be abandoned.

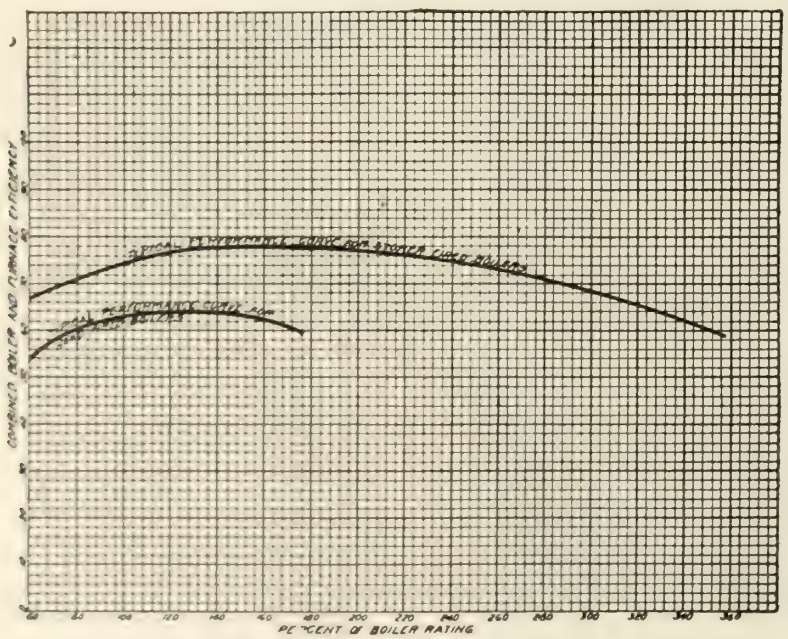

Fig. 5.—Calculated Performance.

Level Fuel Bed

The striking feature of the new stoker is a level fuel bed, which does away with the causes of uncertainty of the fuel movement. A positive feed of the fuel is provided, giving for the first two-thirds of the travel an upward and rearward movement, and for the remaining one-third a horizontal push to the dumping device.

Retorts and Tuyeres: Are for the first time placed horizontally, and the thickness of the fuel bed, together with its rate of movement to the rear, are at all times under the control of the operator.

Auxiliary Pusher: An auxiliary pushing device of entirely new design is provided. It is so proportioned as to give a graduated retardation to the movement of the fuel as it approaches the dump, and the movement is adjusted to suit different grades of fuel. The positive and continuous movement of the pushing device prevents the formation of large clinkers, delivering the refuse to the dump in comparatively small sizes.

Mechanically Driven Rams: Fuel is delivered to the retort by means of heavy crank-driven rams. The connecting rods operate through specially designed boxes provided with a lost motion arrangement which permits an adjustment of the length of travel of the ram from no movement to full stroke. This permits the instant release of any ram, or all the rams can be run at short stroke for very light loads. When fires are banked, all rams can be left standing in, preventing back-firing to the hoppers.

Air Distribution: Of equal importance with distribution of fuel is distribution of air. The latter must flow through fixed openings to the fuel bed. It is evident, therefore, that the greater the number of retorts in a given space, the easier it is to effect an intimate mixture of fuel and air. The Detroit Underfeed Stoker has narrow retorts spaced as closely together as mechanical construc-

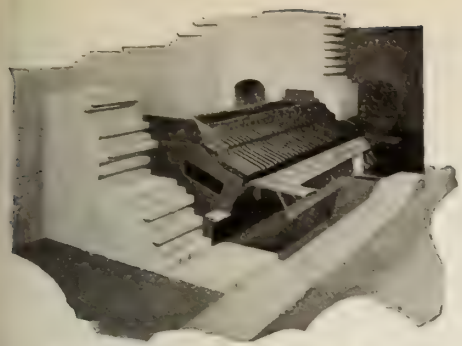

Fig. 6.—Rear view Detroit Single Retort Underfeed Stoker.

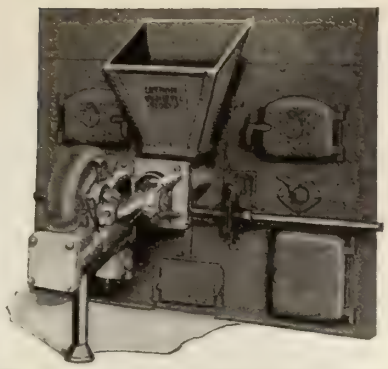

Fig. 7.—Front view Detroit Single Retort Underfeed Stoker.

tion permits. Tuyeres are simple in design with numerous openings arranged to discharge air evenly throughout the fuel bed, and so spaced that all parts of the bed can be reached with comparatively low air pressure.

Regulation: For best results it is essential that the feeding of fuel and the supplying of air be properly co-ordinated. In the Detroit Underfeed Stoker much thought has been given to constructing a machine that in operation will bring the air and fuel into intimate relation in proper proportion for complete combustion. Means have been provided for maintaining this proportion as the rate of feeding and burning alters. Any of the present systems of automatic stoker control can be used in connection with the Detroit Underfeed Stoker. In addition to the automatic control, the independent hand control of each ram enables the operator to shape the fire properly and to maintain it in proper condition for best results at all times.

Automatic Operation: One of the principal requisites of satisfactory stoker operation is that it shall be automatic as far as possible. It is, however, a fact well recognized by power plant engineers that the human element must enter into the operation of a stoking machine. This is due to sudden changes in load, fuel and many other factors, all tending to increase or decrease the fuel consumption. The Detroit Underfeed Stoker has been made as nearly automatic as the conditions of combustion permit. The principles of design and construction employed render it extremely responsive to automatic control. The designers have had the operator in mind and have given him every aid in the way of simplicity of operation, to the end that he can readily understand and manipulate the stoker.

Efficiency and Capacity

The chart, (Fig. 3), shows a typical test performance of the new Detroit Underfeed Stoker at capacities ranging from 60 per cent. to 350 per cent. of normal boiler rating. It will be seen that the combined boiler and furnace efficiency drops a little as the load increases. This indicates a high degree of economy under normal load conditions and a very high and economical reserve capacity to meet unusual loads.

Flexibility

The extreme flexibility of the new stoker is indicated by the chart, (Fig. 4) taken from actual test. This test was made on a 500 H. P. water tube boiler. The fire had previously been banked for four hours, with the boiler developing only about 10 per cent. of its normal rating. From this test it will be seen that one minute after the heavy load was placed on the boiler it was developing normal rating and within two minutes it was developing 200 per cent. rating and within four minutes a rating of 300 per cent. which was held without difficulty. The ability to meet peak loads quickly is of the greatest importance, as far as stokers for central stations are concerned, and it is even of almost equal importance in large industrial plants, particularly those where quantities of steam are at times required for manufacturing processes. In particular when the number of boilers in a plant is limited, extreme flexibility on the part of the stoker installation is an invaluable asset.

Calculated Performance Curves

A comparison of the calculated performance curves, (Fig. 5) of the new stoker, with the actual test curves, (Fig. 1), shows the results achieved in practice to exceed those theoretically determined. The ability to meet performance guarantees readily is of course, extremely desirable, and the new stoker has so far fulfilled every expectation in this respect.

Single Retort Side Cleaning Stoker

The single retort, side cleaning stoker, (Figures 6 and 7), is designed on the same principle and possesses all of the advantages of the multiple retort stoker just described. It differs in design from the latter however, in the location of the dump, which is placed on the side. This dump is hand operated and refuse can be removed either through ash doors in the front, or delivered below to a hopper or ash conveyor.

The arrangement for admitting air, under control through specially designed tuyeres at both sides of the retort, produces a high overload on quick demand. The regulation of feed of the coal and removal of the clinker and ash are both accomplished without interference with operation of the stoker.

This smaller stoker has a mechanically driven plunger or ram operated by reduction gears from a shaft below, driven by a small engine or motor. All gears, worms and moving parts are fully enclosed, running in oil and are easily accessible. The simplicity of the design without any moving in the fire, insures a minimum maintenance cost.

The control of the air in the wind box and the convenient arrangement for regulating the amount of coal to be burned in accordance with the load required, produces a uniform steam pressure in the boiler.

ARTIFICIAL DAYLIGHT

One of the most interesting problems in illumination is to provide an artificial source of light which will exactly reproduce ordinary daylight. One way of obtaining the desired result is to filter the light of an electric or other lamp through special glasses, but a British inventor recently produced another form in which all the light is reflected from an umbrella shaped reflector on which patches of certain colours are painted. All the light used comes from this reflector and is modified by the colours to give a very exact imitation of daylight. An improved form of this artificial daylight apparatus has just been patented. The reflector consists of two layers of material perforated with holes so that a certain number of spots of the colours are exposed. Radial strips of another colour are placed over the perforated layers, the whole arrangement being mechanically strong and giving the correct areas of the various colours to provide artificial daylight.

BRITISH TRADE SHIP

Some time ago arrangements were completed for the building of a special vessel to act as a floating exhibition of British manufactures. For various reasons the voyage of this ship has been postponed for a year or two. Meanwhile a large British liner has been acquired for the purpose of being converted into a trade ship. The cabins will be used for the accommodation of the representatives; and the holds and other portions of the vessel will be adapted for exhibition purposes.

MONEL METAL FOR VALVES

Monel metal resists the eroding and corroding effects of hot steam, has a comparatively low co-efficient of expansion, and one which agrees very closely with that of cast steel. These three qualities make it particularly suitable for the seats, discs or other wearing parts of high duty valves. The non-corrodible feature causes resistance to superheated steam, the expansion similar to steel keeps the seats in the same relation to the steel bodies usually used for these valves, and the comparatively low expansion brings about retention of size and shape at all times. For this reason it is widely used, and a majority of the higher class high duty valves are trimmed with monel.

R. P. Ross & Co. of Sudbury, have secured contracts on behalf of the Standand Steel Construction Company Limited, for all the construction steel work on the Copper Cliff school and the Salvation Army citadel, Sudbury.

Buying Stoker Replacement Parts

By RUSSELL T. GRAY

From "Combustion."

THERE is no other piece of equipment in the modern plant that is worked as hard as the stoker—and abused as much.

And yet, all the better-known makes of mechanical stokers stand up remarkably well under long overloads and abuse. When replacements of wearing parts are necessary, however, spare parts should be ordered with the same care that marked the original purchase of the stoker.

New equipment is not bought by the pound, like so much cast iron. The man who buys a stoker buys the raw material plus the engineering skill and experience that is necessary to shape that material into the smoothly-functioning apparatus that he wants in his plant, which may be the result of years of patient, day-after-day striving for betterment.

Just as a great painting is judged by the "brains that are mixed with the paint" and not by the amount of paint daubed on the canvas, so is the worth of engineering equipment determined by the "brains that are mixed with the cast iron."

This is just as true of replacement parts as it is true of the original stoker. Spare parts that are not made by the same maker as the stoker, are only so much cast iron without the brains—and worth no more than the current market price for castings.

Some engineers order spare parts from local foundries, in the belief that a penny saved is a penny earned. High freight rates have tended to increase such local buying, with the results that many stokers repaired with parts cast at local foundries are falling down under the daily grind, not because of stoker faults but because the new parts interfere with the proper operation, rather than help.

Many complaints received by stoker manufacturers are directly traced to poorly fitted pieces made locally, which at first might be considered of little consequence. But when the perfect operation of every part of a machine is dependent on perfect operation of every other part it may be easily understood why one misfit causes unending trouble with all the working parts. It is absolutely necessary that spare parts fit accurately, and only parts made by the original manufacturer can be depended on to answer these requirements.

Stoker parts that are subject to intense heat are usually made of a grade of iron or steel, which has been found to give the longest service under the particular conditions surrounding that part. When these pieces finally burn out, the engineer who orders replacement parts from his local foundry usually finds that the new parts he has bought soon burn out or begin to warp and buckle. This is because such castings are made of ordinary gray iron, like window sash weights, which cannot withstand the high temperatures.

The engineer who understands that the main spring in his watch cannot be cast iron, but the highest grade of crucible steel, realizes that all iron or steel is not the same.

Every stoker manufacturer maintains a service department with the sole object of making replacements at the lowest cost to user and keeping equipment operating satisfactorily. The reputation of the manufacturer is behind every extra part sent out by service department. If it doesn't fit or doesn't wear, the manufacturer makes good. If the locally-made casting isn't right, the engineer holds the bag.

New improvements that are added from time to time are sometimes incorporated in old stokers by the service department so that the engineer who buys parts from the manufacturer keeps his stoker up-to-date at very little extra cost.

It's a rather serious affair when a man's heart stops beating. And sometimes it's almost that serious when a stoker stops stoking. Therefore it would seem to be clear that enough spare parts should be kept on hand to insure continuous operation. Better too many spare parts, that fit, than a carload that do not fit.

New Suspended Arch

THE advent of the mechanical stoker brought in its train problems relating to brickwork in the furnaces, and of the overhead arch in particular. There have been many developments of this arch, the suspended type gradually being evolved. We illustrate here one of the latest types of suspended arch, made by the Murphy Iron Works, Detroit.

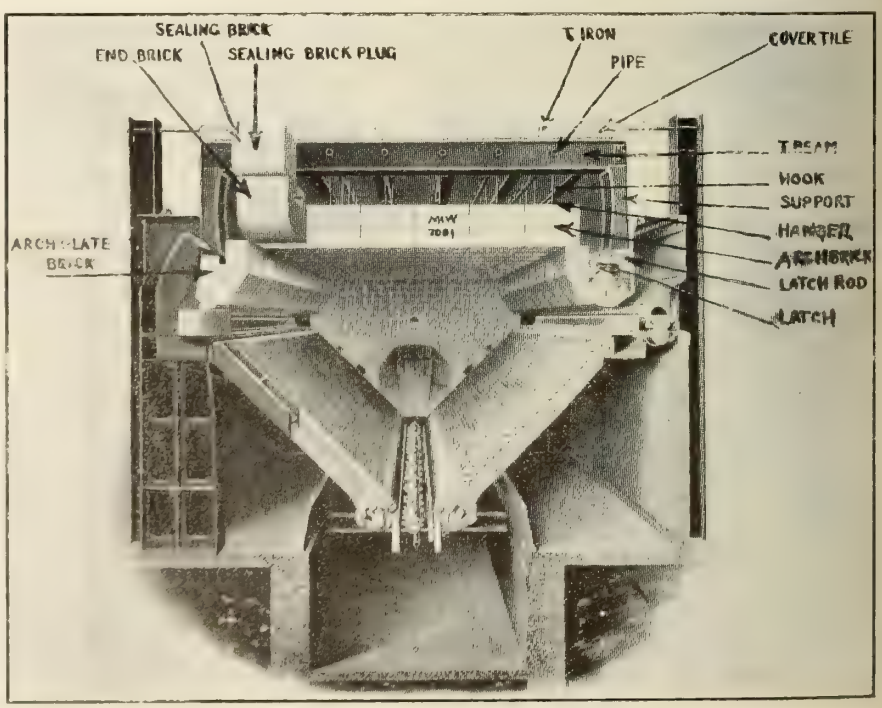
The illustration gives the idea pretty clearly, and the brief description will supply the rest of the information needed to understand the principle.

The arch consists of a number of slotted blocks, each independently hung from longitudinal pipes, which are in turn supported from transverse I beams. The pipes are perforated at the rear end, and open at the front, and the furnace draft draws air through these pipes, keeping them cool, and delivering the air in small jets at the point where it is most needed.

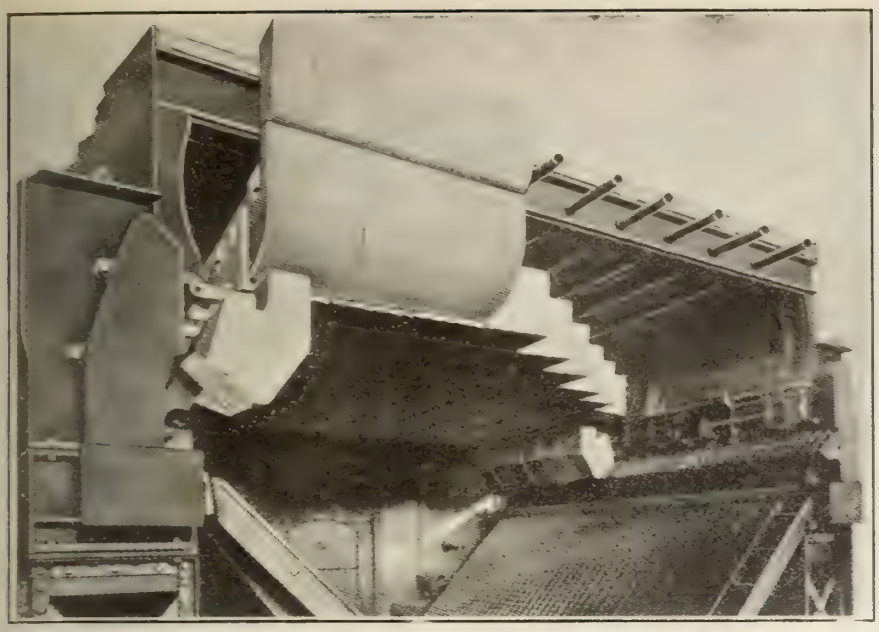
The space at the rear of the arch is closed by two special blocks, so attached that they cannot be forced off the supporting members by the expansion of the arch.

The arch plate bricks are also independently supported and can be quickly removed and replaced without interfering with any other portion of the arch. The air space above the fire brick arch is covered or closed by cover tile resting upon T irons and arranged with deflector plates to insure the correct distribution of air. The arrangement for air distribution and cooling the arch has been carefully designed as the result of long experience in the design and construction of furnace arches.

Every brick in the arch is independently supported and can be removed and



General Arrangement of Arch

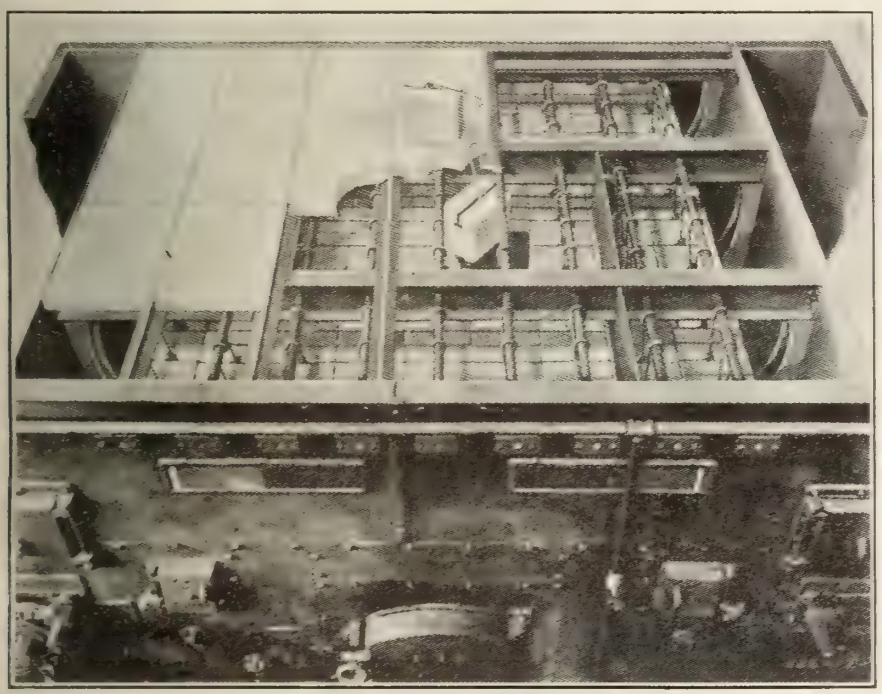


Showing arrangement of front blocks.

replaced without disturbing the balance of the arch.

An arch generally requires repairing rather than the renewal of the entire arch, and if a local deterioration can be repaired easily and inexpensively the life of the arch is lengthened many times.

By referring to the illustrations, it will be seen that by simply lifting off the cover tile, any brick in the roof of the arch may be removed and replaced without disturbing any other brick and this, if desired, can be done while the furnace is in operation.



View on top of arch looking down.

ARMATURE PRESS

An armature press that is intended for the use of electrical repairmen has recently been placed on the market. The construction and capacity of the press enable it to be employed for assembling operations such as putting in place piston flags, spindle bushings, gears and similar work. The frame is of cast steel and is capable of withstanding a pressure of 3,000 pounds. It is 17 in. in height overall, and an opening provided in the base is 5 in. in dia. A hardened steel plate, made in two pieces, having three different sizes of openings is furnished to accommodate small work. The plate is held together by two bolts. The two halves can be slipped under the bearings of an armature shaft so that the shaft can be pressed out of the bearing. The working height between the plate and the bottom end of the arbor, in the raised position, is 9¾ in. The press is manufactured by the Napier Machine Co., Inc., of Napier, Ill.

A RECORD CASTING

The largest iron casting ever made in reat Britain and one of the largest ever produced in any country was recently turned out in a British factory. It weighed 110 tons and the mould was built in a 16 foot pit. Seven hours were occupied in melting the metal, and the casting was poured in just under five minutes. Three weeks were occupied in cooling the casting. Owing to its enormous size and weight the casting had to be delivered by road, six traction engines being used for hauling it.

PORTABLE BENCH SAW

A portable bench saw that is adapted particularly to light work in cutting and fitting wood parts, has recently been placed upon the market. The machine is motor driven and is self contained. The base carries a one piece table upon which the motor and saw are mounted. The table and saw can be swung to any angle up to 45 deg., in either direction. This feature is very useful in cutting moulding for mitre joints. The motor and saw are mounted on a frame that swings about a horizontal axis. The saw is normally kept in an elevated position by means of a coil spring. The power is transmitted from the motor to the saw arbor by means of a belt, which is provided with a screw adjustment to maintain the proper tension. The belt and pulleys are fully protected by a metal guard. The saw has a combination of both large and small teeth. A metal housing covers the saw, and from the front of this housing there projects a handle for depressing the saw. The motor control switch is near the saw control handle, on the metal saw guard. The bottom of the saw is protected by a metal guard on each side of it. When the saw is elevated the guard is locked in position, so that the saw teeth cannot come into contact with the work accidentally. These guards can be unlatched by a motion of the right forefinger, just previous to commencing the cut. A small chute is provided at the rear to carry away all dust. A permanent gauge for positioning the work is secured on the stationary bed. The swiveling table can be locked in any desired positon, and it is possible to lock the saw at any height. The saw is manufactured by the Tannewitz Works, of Grand Rapids, Mich.

Construction work on the new extension to the Port Arthur plant of the Provincial Paper Mills has been started. The cost of this addition will be in the neighborhood of $1,500,000.

The contract for the construction of a cooling plant for Swift Canadian Packing Co. of Ottawa, has been awarded to Joseph Robert at an approximate cost of $10,000.

Refrigeration For the Power Plant Engineer

This Article, the Second of a Series of Six, Explains the Principle of the Compressed Air Refrigerating Machine, Taking up Heat and Rejection of Heat at Different Temperature Levels

By T. H. FENNER

WE HAVE seen that in order to change the state of a body, or a gas we must either give up or absorb a certain amount of heat, which is partially made up of sensible heat, which effects the change of temperature necessary to bring the body to the point of fusion. The remainder of the heat given up or absorbed has no effect on the temperature, but is latent in the body or matter or gas.

If we place a block of ice in the ordinary household refrigerator, the ice being at a temperature of 32 degrees, and the refrigerator at say the temperature of the room it is in, which may be considered at 70 degrees, the ice immediately begins to take up heat from its surroundings. These include the air in the refrigerator, and the contents. Suppose the block of ice weighs 50 lbs., then in order change it into water at 32 degrees, we shall have to absorb from the refrigerator contents 144 x 50 7200 B. T. U. If we consider the contents as dropping to 32 degrees, that is 38 degrees of temperature drop, there would be enough heat absorbed by the ice to cool 188 pounds of matter to 32 degrees. We know that the 50 lb. block of ice will not produce such results. Why? Simply because as soon as the inside of the refrigerator becomes at a lower temperature than the air in the room, heat starts to infilrate through the walls of the refrigerator itself. This heat has to be taken up by the ice and this adds an appreciable amount to the total heat. In other words while the ice is absorbing the heat in the refrigerator, more heat is being added to it by infiltration. Every time the doors are opened to take out food or place fresh food in, there is a fresh accession of heat, which raises the temperature. These losses are variable and hard to compute. If we had perfect insulation, and double doors that would minimise the amount of heat getting into the "frig." every time it was necessary to place or remove food, we should get a considerably larger amount of cooling effect from our block of ice.

Now if we could keep adding just the amount of ice necessary to counterbalance the heat infiltration, we could keep our refrigerator at the same temperature indefinitely. That is not possible, but if we can use some other means instead of ice, such as a cold liquid and keep it circulating through the frig., taking the accrued heat out of it at each cycle of revolution, and sending it back again to absorb heat again, we would have the desired result. This is exactly what is done by a mechanical refrigerating machine. The cold liquid gives up its heat to the refrigerating medium which is in the form of a liquid, and which is changed to a gas by the absorption of heat from the cooling medium. This heat is taken up by the cooling liquid from the air or goods that have to be cooled, and the cycle of heat rejection and absorption continues as long as the machine is running. In many cases the gas itself is the direct medium for taking up and rejecting heat, and in order to understand how this is possible we shall consider the matter in more detail.

The Air Machine

Outside of early machines which employed the absorption of heat caused by chemical mixtures, the first commercial machines were those that employed the compression and expansion of air. The machine in general consisted of a steam cylinder which furnished the motive power. In connection with this steam cylinder were two air cylinders, driven from the same crank shaft, or in some cases arranged in tandem, which were used for the compression and expansion of the air. These two cylinders were fitted with ordinary slidevalves, arranged to cut off at a definite point of their stroke. The first or compression cylinder was of much smaller diameter than the second or expansion cylinder. These cylinders were double acting just as the steam cylinder, and we can consider the action at one end only as illustrating the whole cycle. On the suction stroke of the high pressure cylinder, air was drawn in until the point of cutoff was reached, just as in an ordinary air compressor. On the return stroke this air would be compressed, being raised to a certain pressure and temperature, when the exhaust valve would open, the compressed air passing to the piston of the low pressure cylinder. Now let us see what has taken place so far. A certain quantity of air has been raised from atmospheric temperature and pressure to a pressure and temperature considerably above the atmosphere, by reason of the work performed on it in compressing it. Here we have the work appearing in the form of heat in the air. The high pressure cylinder being surrounded by a water jacket, a certain amount of the heat would be carried away by the circulating water, sufficient to prevent the cylinder walls from getting to an unworkable heat. On leaving the high pressure cylinder still at fairly high temperature, the air passed round another coil in which water was circulating, still more of the heat being carried off by the water of this coil. The air on reaching the chest of the low pressure cylinder would be then at approximately the same pressure as it had when leaving the high pressure cylinder, but at a temperature considerably less than that due to its pressure. It is then admitted to the cylinder, and when a certain portion of the stroke has been made the slide valve closes. The air then expands for the remainder of the stroke, doing work on the low pressure piston and in doing so it gives out about the same amount of work as has been done on it in the compressing cylinder. This means that it gives up about as much heat as was given to it by the work done, but as the heat of compression has been carried away by the circulating water, and the air in the low pressure cylinder is at about atmospheric temperature at the beginning of expansion, its final temperature is a great deal lower than that of the atmosphere. This cold air is then discharged from the cylinder and conducted through pipes to the rooms to be cooled. These being at a higher temperature than the air in the pipes, heat is absorbed from the rooms, and is carried away by circulating air, which goes back to the high pressure side to be passed through the cycle again.

Now this is the cycle in any refrigerating machine. Heat is added to medium at one stage of the cycle, it is rejected at another, and in the third an amount of heat equal to that rejected is taken up again. But, some reader will say, this brings us back to where we started. This is an assumption which may easily be made but a little further examination will show where it is wrong. If the addition and subtraction of heat were made at the same temperature level, this would be quite true. Let us take our air machine again. Air at atmospheric pressure and temperature has work performed upon it which increases its pressure and temperature. The work necessary to overcome the internal resistance of the air to compression is absorbed in the air, while the remainder of the work appears in the form of a high temperature. This heat is carried away in the cooling water, leaving the air with an amount of heat about equal to its initial temperature plus the heat due to the work of overcoming the internal resistance of the air. If this air were allowed to expand slowly to its original pressure, the amount of heat that was taken up by the air itself to compress it would be sufficient to accomplish the work of expansion. However the air in expanding is allowed to do work on the piston and this work is equivalent to a certain amount of heat. This heat is taken from the temperature of the air, which results in the temperature being lowered considerably. When the cold air passes to the room to be cooled, it takes up heat, but this heat that is added only

somewhat lower than the temperature of the room. Thus we see we have added heat first at high temperature, rejected heat at high temperature to the circulating water, and then given up heat by doing work, causing a further drop in temperature, and finally have again taken up heat at low temperature.

Internal Work

As a simple illustration of what is meant by the internal work absorbed or given out in overcoming internal resistance of a gas to be compressed we may take the familiar case of steam raised from water at 32 degrees to atmospheric pressure. If we take one pound of water it will occupy a volume of 1-62.5 part of a cubic foot. Steam at atmospheric pressure requires a volume of 26.36 cubic feet. Suppose we have one lb. of water in a vessel one square foot in area, and 26.36 feet high, the water being at a temperature of 32. Let the pressure of the atmosphere on the surface of the water be represented by a frictionless piston, having a weight equal to 147 lbs. per sq. inch. When the water has been evaporated to steam at atmospheric pressure the vessel will just be filled, and the piston will have been raised from a height of .016 feet, the level of the surface of the water at the beginning to a height of 26.36 feet. If the piston weighs 14.7 lbs. the work done is the product of the resistance overcome by the distance, or 14.7 x 144 26.36. The height of the water .016 feet is so small a fraction of the total that it can be neglected. The work done is then 55,-799 ft. lbs. and this divided by 778 gives 71.72 B. T. U. as the heat required to overcome the external resistance or the resistance of the atmosphere. Now the total heat units expended have been 1.146 B. T. U. 180 to raise the water from freezing to boiling point, which sensible heat, and 966 B. T. U. latent heat. In overcoming external resistance we have expended 71.72 B. T. U.

We have therefore the following distribution of heat in evaporating one pound of water from 32 to steam at 2.12 degrees.

Raising temperature of water 180 B. T. U.

Overcoming internal resistance 894.28 B. T. U.

Overcoming external resistance 71.72 B. T. U.

ANOTHER SUGGESTION

Editor, Power House:—

I have read with interest all letters regarding "The Dominion Certificate," and also the suggestion of C. T. M. of March 20, 1922. I really believe that C. T. M. is asking the government too much in asking them to give every holder of a certificate a "Dominion Certificate" of the same grade. I have been employed at different places and have been in contact with a good many engineers, and I could not see for the life of me how some of them ever got a First or Second Class certificate. If these same men had to sit over again perhaps they could get a third and perhaps not. Examinations in the olden days, (as we all know), were not what they are today. Then if we do approach the government, suggest to them when they do pass this law to have all engineers sit over again for the "Dominion Certificate." This is also offered as a suggestion.

Editor's Note

This question is one on which there would naturally be very wide diversion of opinion, some favoring the granting of a certificate equal to the one already held, and others feeling that no certificates should be granted except on examination.

We feel in this matter that in the case of men holding positions successfully, the passing of new legislation should not be allowed to work them injury. Common sense insists that if a man has been running a job for a number of years he must be competent, certificate or no certificate. It is different for those just coming up, but it would be a positive injustice to ask a man to pass a theoretical examination, after he has spent a large portion of his lifetime working hard at the practical end of his business without the opportunity of gaining the theoretical knowledge. The object of improved certificates is to improve the general standing of engineers, which can be attained without harming anybody, and should be done in that way if it is to be done at all.

There is one thing which continually bobs up in correspondence, and one which we think should be eliminated, not only from the correspondence, but from the thoughts of the correspondents. We mean the constant repetition of the opinion that the other fellow has a certificate which he should not have. Our correspondent above says, "he does not see for the life of him how they ever got a first or second certificate." The other fellow may have been thinking the same.

We should remember this. A man holding a certificate has complied with the regulations of the authority issuing that certificate. He can do no more. He may be able to pass a much harder examination, on the other hand he may have just scraped through. In the latter case he deserves more credit than in the former, for he has had to put in a good deal more effort.

The thing is this: When we meet a man who is obviously not so well informed as ourselves, let us help him instead of sneering at him. Remember that old fable of the lion and the mouse. Be charitable.

FACTORY INSPECTION

Editor, Power House:—

Having read the article in April 5th issue re factory inspection, I think it about time that the factory inspection department realized that the factory workers of Ontario are entitled to some degree of protection. It is purely criminal the way the factories of this province are inspected. I was employed by a concern where a new plant was built and put into operation and nearly four years passed before a factory inspector showed up, and then he might just as well not have come, for all the good he did. There were a great many things that needed his attention but all of them went unnoticed by him.

What we want are men who are wide-awake to the interest of the people employed in the factories of this province and not men who just merely draw their salaries. As you stated what we want is a department that will inspect. I can assure you that from the many things that have come under my personal notice in different plants I have visited, I think it high time for a change that will give the factory workers of Ontario the protection to which they are justly entitled.

I have the honor to be, yours for a square deal, "Onlooker."

WATER WHEEL CORROSION

In the water wheel work the blades of the wheels travel at very high speeds. The combined effect of the evacuation resulting from this high speed and the corrosive action caused pitting in bronze, this pitting being sufficiently deep to bring about failure. Monel metal replacing such bronze has shown more than 9 years' service without a sign of pitting.

Industrial consumers of coal in Ontario have shown no sign yet that they fear a shortage of bituminous coal, as a result of the strike that has been in progress since April 1. The situation has been remarkably quiet, as regards operators, miners and consumers. The Canadian situation is causing little comment. The general view is that the long notice given to consumers gave them an opportunity to secure adequate stocks, and that there is no occasion for worry for some time yet. The large industrial users of coal in particular have protected themselves against almost any contingency.

Great interest is being shown in the discovery of a new metal, non-ferrous in character, and known as "Virtu." The new material dispenses with electroplating, does not tarnish, and is considerably less than half the cost of stainless steel ware. Experiments are now proceeding in the steel works to decide whether the discovery can be applied for engineering purposes. Exhaustive tests have proved that the material can be rolled or cast. The inventors are hoping to prove that it can also be forged or hot rolled like steel, in which case it could be applied to a hundred-and-one uses in constructional trades, as, for instance, turbine blades, agricultural machinery parts, and motor-car fittings, which are particularly liable to corrosion through exposure.

Practical Electricity For the Engineer

By G. R. ARCHDEACON, A.M.I.E.E.

AS ALREADY explained in the last chapter, current density is always expressed in "amps per sq. inch."

Many different strengths of current may be sent through the conductor of a certain sectional area. This current, or rather electricity, may (for practical purposes) be said to permeate the substance of the conductor, and the greater the current value, the higher will be the "current density."

It must now be clearly understood that this question relates solely to the current in the conductor, and in no way does it relate to the pressure, or voltage at which the current is being "forced" through the conductor.

When a given current has to be carried, the conductor must be of such a size that the "current density" does not exceed a certain number of "amperes per sq. inch." The reasons for such limits are as follows:—

(a) The greater the "current density" in a given conductor, the greater the amount of heat that will be generated in the conductor.

(b) The greater the "current density," the greater the "loss of pressure" or "loss of voltage" with consequent loss of power.

From a consideration of the above reasons it will be apparent that in distributing current, it is necessary to carefully calculate the most economical "current density." Thereby permitting the choice of the smallest size in wire, consistent with value of the amount of power lost in that wire. It will be readily seen that it is possible to choose a conductor with such a sectional area that the amount of power lost per annum would be almost zero. The extra cost of such a conductor would be so much greater than a reasonable loss in power would involve.

The marine engineer has to find the "economical speed" of his ship and contrive to keep her running as near that speed as possible. Similarly so has the power engineer to calculate the "economical size" of his cables for distributing his electric power.

The late Lord Kelvin established a law governing these conditions, which is usually accepted amongst electrical engineers.

"The most economical size of conductors is that for which the annual cost of interest and depreciation is equal to the cost of energy dissipated in the conductor."

In other words, every unit of electrical power has cost a certain sum of money, and the amount of the cost of the electrical power lost in the conductor per annum, should just amount to the value of the annual depreciation allowance on that conductor, plus the amount of interest payable on the cost of the conductor.

If the conductor is "overloaded" there is a great increase in temperature, which may result in the burning of the insulation, or even melting of the conductor itself.

In this connection it is very important to bear in mind that the rate of generation of heat is proportional to the "current squared multiplied by the resistance."

Voltage Drop Round a Circuit

As in the case of steam or water there is always a loss of pressure in the various conductors, and so in any electrical circuit the volts drop in value round the circuit.

It is important that this fact is not overlooked, otherwise in laying out a scheme for lighting some workroom a distance from the power house ,the "drop in volts" may be so great that the resultant illumination from the electric bulbs will be so reduced as to be merely darkness visible.

Suppose we consider a circuit which has a difference of potential of 100 volts. If we connect a voltmeter across the ends of the circuit we shall obtain a reading of 100 volts, but if both voltmeter wires were brought into contact with the same end of the wire, the voltmeter would register zero voltage, because there would be no difference of potential at that point.

If the conductor of this circuit is made throughout of the same material, and same diameter, the fall of pressure, or volts drop round that circuit will be uniform. Thus, one quarter way round the circuit, the volts on the voltmeter would register 25 volts, half way round 50 volts potential difference.

The pressure falls gradually all round the circuit, if the latter be uniform.

The fall of pressure in any part of a circuit carrying a given current is proportional to the resistance of that part.

Generally we find that certain parts of a circuit have a greater resistance than other parts. Take for example a simple circuit containing a single electric bulb. If we test the voltage across the main terminals of this circuit we find say, 100 volts potential difference across V. Again take a reading across VI and we obtain a difference of potential of about 99.5 volts. (Fig 1).

From this experiment we see that we have actually only lost half a volt along the wire, whilst through the lamp we have lost or caused to be dissipated 99.5 volts. This being due to the fact that practically all the resistance of the circuit is concentrated in the lamp, whilst the resistance of the wires or conductors is practically negligible.

Now connect two electric bulbs in series across 200 volt circuit. And if the lamps are each of the same candlepower and of the same resistance there will be consumed within each lamp 99.5 volts because the length of the circuit will not be sufficient to cause a drop of half

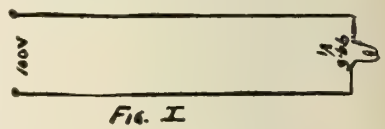


Fig. I

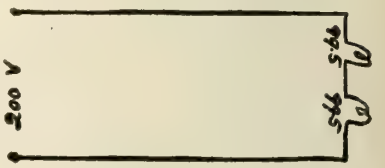

Fig. II

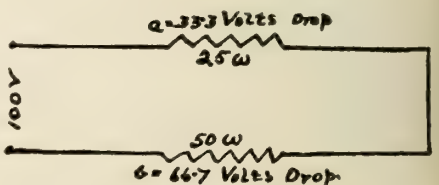

Fig. III

volt. This exaggeration is purposely made to emphasize this point.

The Current in Each Part of a Series Circuit Requires Pressure in Proportion to its Resistance

It will be quite apparent from the above statement that the pressure is consumed in proportion to the amount of resistance, and should this resistance vary along the circuit, so also will the drop of pressure vary in each resistance.

For example let it be supposed that the resistance of the circuit (Fig. 3) is chiefly concentrated at a and b, and that a has a resistance of 25 ohms, and b a resistance of 50 ohms. The resistance of the connecting wires being negligible. The total pressure of 100 volts is thus mainly taken up in forcing the current through the total resistances of 25 ohms plus 50 ohms or a total of 75 ohms.

The pressure drop through the whole 75 ohms is 100 volts.

The pressure drop through a $\frac{25}{75}$ of $\frac{100}{1}$ is 33.3 volts.

The pressure drop through b $\frac{50}{75}$ of $\frac{100}{1}$ is 66.7 volts.

Whenever a Current Flows Through a Conductor There is a Drop of Volts Proportional to the Current and the Resistance of the Conductor

This rule is merely the application of Ohm's Law to a part of the circuit, and may be expressed as follows:—

Volts drop = ohms × amperes.

If the volts drop and the current be known, the resistance can be found:—

$$\text{Ohms} = \frac{\text{volts drop}}{\text{amperes}}$$

$$\text{Amperes} = \frac{\text{volts drop}}{\text{ohms}}$$

Power in a Circuit

When current flows round a circuit containing lamps or heaters, etc., it is sometimes a puzzle that it should be the same at the end as at the beginning of the circuit. Light and heat have been given out, therefore something must have been absorbed.

Something certainly has been absorbed, what is it?

It is pressure that is absorbed in the circuit, especially in those parts which have the greatest resistance, such as where the light or heat is generated.

As already demonstrated the absorbing of the pressure in the circuit is manifested by the voltage drop through these various current consuming devices.

Pressure, however, alone is not sufficient. It is pressure and current which has been turned into light and heat, in other words electrical power. This is the product of the two quantities, volts and amperes and are known as "watts."

Voltage multiplied by amperes equals watts.

The "watt" is therefore the "unit of electrical power," or rate of doing work.

In lighting a lamp or warming an electric heater, work is said to be done, and power is absorbed.

Watts = volts × amperes.

$$\text{Volts} = \frac{\text{watts}}{\text{amperes}}$$

$$\text{Amperes} = \frac{\text{watts}}{\text{volts}}$$

The watt being such a small unit it is frequently necessary to employ a larger unit, this known as the "kilowatt," and is equal to 1,000 watts.

As above stated, electrical power is absorbed in any circuit in doing work but this power is reproduced in the form of light or heat energy and so cannot be considered as lost.

Mechanical power is generally expressed as Horse Power, or h. p.

The relation of the electrical horse power to the mechanical horse power is very simple:—

746 watts = 1 h. p..
1 kilowatt = 1.34 h. p.
1 h. p. = 746 watts.
1 h. p. = 0.746 kw.

To arrive at the power consumed in a circuit there is also another method, providing there is no counter electro motive force, such as obtains in circuit in which there are motors or storage batteries.

This method is to **square the current and multiply the result by the resistance.**

$I^2 \times R$ = watts.

Example:—

What horse power would be required to send a current of 200 amperes through a resistance of 2 ohms?

First Step:—

Find power in watts.

$I^2 \times R$ = watts

200 × 200 × 2 = 80.000 watts.

Second Step:—

Find h. p.

1 h. p. = 746 watts.

$\frac{80{,}000}{746}$ = 107 h. p. (approx.).

In sending this current through the resistance we have calculated the h. p. necessary. Now what has become of that h. p.? It has been dissipated into heat by the warming up of the resistance.

In studying the various problems relating to the energy in steam, the power house engineer has become familiar with Joule's mechanical equivalent of heat. There is a close connection between joules and watts, which must now be considered.

The smallest practical unit of electrical work is the joule, a larger unit is the watt-hour, and a still larger unit is the kilo watt hour.

Multiply watts by seconds to get joules.

Multiply watts by hours to get watt-hours.

Time must always enter into any estimation of work done, or energy consumed. If a circuit absorbs 1 watt for 1 second, we can say that 1 joule of work has been accomplished.

10 [watts for 5 min.= 10 × 5 × 60 secs: = 3,000 joules.

Heat is a form of energy, and if an electric circuit contains no counter electric motive force, (e. m. f.) that is to say, if there is no motor or storage batteries under charge, no electrolytic apparatus, or no inductive effect as with alternating currents, the whole of the electrical energy expended in the circuit will be converted into heat energy. If there is a lamp in the circuit, a small portion of the heat energy will be converted into light.

The unit of heat is the British thermal unit, and is the amount of heat required to raise 1 lb. of water 1 degree Fahr. when at its maximum density.

This quantity may be expressed electrically as follows:—

1 B. t. u. = 1,055 joules.
1 B. t. u. = 0.29 watt-hour.

The heat generated in a circuit may be expressed in B. t. u.'s by the following formula.

Let E = volts. I = amperes t = time in secs:

$$\text{B. t. u.'s} = \frac{E \times I \times t}{1{,}055}$$

It will readily be understood that the B. t. u's required to heat a given quantity of water to a given temperature, much will depend upon the efficiency of the heating vessel, this will depend upon three things:—

(a) The proportion of heat generated which is imparted to the water.

(b) The prevention of loss of heat by the water.

(c) The quickness of generation of heat.

Example:—

It is required to boil 2 quarts of water in 6 mins. If the efficiency of the electric heater is 80 per cent., how much energy will be used? What will it cost if the charge per kw.-hr. is 5c.?

1st Step:—

How many B. t. u.'s are required? Assuming temp. of water 60 deg. Fahr.?

212 deg. less 60 deg. = 152 deg. rise in temp.

Total B. t. u.'s necessary, 2 quarts × 2.5 B. t. u.'s per quart × 152 = 760.

2nd Step:—

Find power required?

Theoretical number of watt-hours required = 760 B. t. u.'s. × 0.29 = 220.

$$\text{Actual watt-hours} = \frac{220 \times 100}{80 \text{ per cent}} = 275$$

If one hour were allowed for boiling it would take 275 watt hours, but it is required that the water should boil in 6 mins. or in 1/10 of one hour.

Therefore watts necessary = 275 watt-hrs.

$\frac{\quad}{0.1 \text{ hour}}$ = 2,750

Cost of boiling will be =

$$\frac{275 \text{ watt-hrs.} \times 5\text{c. per k. w, h.}}{1{,}000} = 1.37$$

As heat is generated in the conductors

conveying the electric power throughout the system, so also does this generation of heat effect the operation of the dynamos and motors used on the system. If the dynamo or motor is overloaded it is shown up by the overheating of the machine, and continued neglect of this warning will result in the burning out of several coils on the windings of the machine.

The conversion of mechanical power into electrical power by a dynamo or of electrical power into mechanical power by a motor, cannot be effected without some loss of power in the machine.

Such loss depends upon the efficiency of the machine. The efficiency of a dynamo or motor is the ratio of the power given out to the power absorbed, and is usually expressed as a percentage.

$$\text{Efficiency of dynamo} = \frac{\text{Electrical power developed} \times 100}{\text{Mechanical power required to drive it.}}$$

$$\text{Efficiency of motor} = \frac{\text{Mechanical power developed} \times 100}{\text{Electrical power required to drive it.}}$$

$$\text{Efficiency} = \frac{\text{output} \times 100}{\text{input}}$$

$$\text{Output} = \frac{\text{input} \times \text{efficiency}}{100}$$

$$\text{Input} = \frac{\text{output} \times 100}{\text{Efficiency}}$$

The efficiency of machines varies with their size, small dynamos and motors are less efficient than large ones. The efficiency of a very small motor may only be 60 per cent., whilst large ones sometimes exceed 90 per cent.

Example:—

500 electric bulbs are required to light a factory, each one taking .25 amp. If combined efficiency of dynamo, and distribution is 86 per cent. efficient, what h. p. will be required to drive the dynamo. Voltage being 100 volts.

Total current required =

.25 amp. × 500 = 125 amps.

Total power required =

125 amps × 100 volts = 12,500 watts.

Total h. p. required =

$$\frac{12{,}500 \text{ watts}}{746} = 16.75 \text{ h. p.}$$

Total h. p. required to drive the dynamo.

If 16.75 h. p. = 86 per cent. of the power put into dynamo.

Let X = the power required to drive the dynamo

Then 86 : 100 : : 16.75 : x

$$\text{Then } x = \frac{100 \times 16.75}{86} = 19.47$$

Total h. p. required to drive the dynamo = 19.47 h. p.

THERMALLY ACTUATED RELAYS

The load capacity of any piece of electrical apparatus is determined by the temperature limits of the materials used in the construction of the device. This characteristic sets a definite maximum load which can be applied continuously.

In many cases, this load can be considerably exceeded for short periods of time without danger to the apparatus. In other cases, a succession of short time heavy overloads can be applied without injury, if followed by intervals of very light load, for the heat developed is integrated over a considerable period of time and the temperature attained as a result of successive short overloads is the same temperature as would be obtained if the integrated loading had been applied continuously for the same length of time.

The Squirrel Cage Induction Motor is a typical example. Such a motor takes a rather heavy starting current, especially if it is of small size and is thrown directly on the line without starting compensators. Fuse protection is generally supplied, but in order to take care of the starting current the fuse capacity must be several times normal full-load running current.

This condition results in the possibility of the motor being overloaded to a considerable extent without blowing the fuses and if the overload continues long enough, the motor may burn out. The fuses then only provide protection against an overload sufficiently great to stall the motor.

This condition should be protected against and the thermal relays recently developed by the Westinghouse Electric and Manufacturing Co., are applicable for this purpose.

The theory of protection demands that an instrument be provided which can be connected in electrical circuits, the instrument to have in itself small losses which are converted into heat and the device should be so arranged that its temperature rises in proportion to the current flowing through the circuit and also designed to embody a considerable heat capacity. The temperature in the relay will then follow approximately the temperature of the apparatus to be protected and the relay can be adjusted so that it will open the circuit when a predetermined temperature is reached.

The relay may be arranged with or without a pointer to indicate its own temperature continuously, and, therefore, the temperature conditions of the protected apparatus, thus giving an idea of the amount of load which has been placed on the apparatus and the increase in load which may be safely applied.

In designing the thermal relay it was necessary to obtain a heat sensitive material which would have sufficient power to operate a contact and still accurately follow changes in temperature. A high grade of thermostatic metal was found satisfactory for this purpose. In order to obtain the greatest simplicity of design, this same material is used as the resister or heat developing element as well as the heat sensitive element.

The operating mechanism of the relay consists of a number of sheets of thermostatic metal arranged in series or in parallel and with varying resistance, according to the desired current carrying capacity. A contact is attached to one of the element and is normally held with an initial tension against the stationary contact. At the proper temperature the bending tendency of the thermostatic metal takes up this initial tension and the contacts open, thus opening the holding coil of a small circuit breaker to open the main circuit.

EXTENDED SLEEVE CLUTCH

A clutch that is intended especially for the driving of wood, steel, and cast iron pulleys, gears, sprocket wheels, or such similar parts placed on the sleeve has been recently placed on the market. It consists of but few parts and is very compactly designed. The friction disc is of large diameter, whch permits of a strong uniform grip, capable of fine adjustment. The spider is either keyed to the shaft or held by a hollow setscrew. The clutch can be erected by merely sliding it on the shaft and tightening one screw. No extra collars are required to hold it together, and as it is self contained it is not necessary to compensate for end thrust. In order to adjust the friction it is only required that one nut be turned, which nut automatically adjusts the tension for both the fingers. The clutch is intended to operate under hard usage with little or no wear, and without noise. It may be placed on a line shaft so that it drives directly to a machine without using a countershaft. In this way considerable space and belting are saved. When used as a cut-off coupling, it enables one group of machinery to be stopped without interfering with other groups. It eliminates the nuisance of shifting belts in many cases. The bearing end of the shaft runs in a bronze bushing that is supplied with oil from the chamber around the bearing. It is manufactured in six sizes from 5 to 12 in. in dia. At 100 r.p.m. the horsepower transmitted is from 2 to 13 depending on the size. The sleeves are from 5 to 6 in. in length. The clutch is manufactured by the L. W. Carroll Manufacturing Co. of Batavia, Ohio.

MAKE SURE

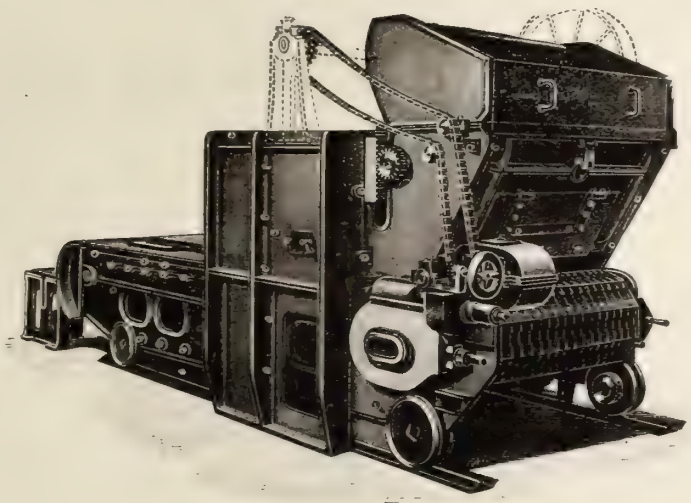
If you're saddled with the notion
That you ought to have promotion,
Don't mistake the mere desire for ability
to rise.

Give the subject more reflection;
It may take a new complexion,
When you view your capabilities with
calm, unbiased eyes.

Find out if you're returning
Value full for what you're earning.
First be sure that you've already done
the very best you could.

Perhaps the time you're wasting wishing
Takes your mind from off your fishing;
If you show a pile of sawdust, we'll
believe you're sawing wood.

"B & W"
MECHANICAL CHAIN GRATE STOKER



YOU CAN SAVE MONEY with a BABCOCK & WILCOX Chain Grate Stoker because you actually burn less good coal than by any other method of firing. Even if you have but 100 Boiler Horse Power it pays because of the coal saved.

You can burn cheaper coal than you will handfire successfully as these Stokers are particularly adapted to burn the smaller and poorer grades.

With handfiring it is difficult to get firemen to take the necessary care and to give the constant attention necessary for complete and smokeless combustion. With the B. & W. Chain Grate Stoker the attendant is not required to work so hard or to expose himself continually to the heat of the fire, and he can apply himself to getting economy.

A good fireman can handfire a 200 H. P. Boiler at ordinary rating, but only the skilled and better-paid men can handle overloads. One man can shovel into the hopper of the B. & W. Chain Grate Stokers all the coal necessary for 1,000 Boiler H. P. or he can attend to 2,500 to 5,000 Boiler H. P. where the coal is fed to the hoppers automatically. Over ratings are obtained with little or no extra effort on the part of the attendants.

Combustion rates may be secured with a B. & W. Chain Grate Stoker which cannot be approached by hand firing methods. The increase in efficiency is the result of the even and continuous firing, the constant air supply, complete absence of the necessity of working the fires and the fact that the coal is burned according to the natural laws of combustion.

WE SHALL BE VERY GLAD OF AN OPPORTUNITY TO DISCUSS YOUR COMBUSTION PROBLEMS WITH YOU

Economy of Cork Inserts

By W. F. Schraphorst

Copyright, by W. F. Shraphorst

THIS IS an important topic that has not been written about or discussed to such extent as have other transmission devices. Why this is so is unexplainable. The principal functions of the cork insert is to stop all unavoidable belt slip. In doing this considerable coal and money may be saved.

Thus where 2,000 tons of coal are burned per year where coal costs $9 per ton, and where the over-all belt slip is 8 per cent., the cost of the belt slip in terms of the coal pile is $1,440. To compute the cost of belt slip it is first necessary to find the percentage of slip. That is, if a driven pulley rotates only 95 times, whereas it should rotate 100 times, the percentage of belt slip is 5 per cent or,

$$\frac{100-95}{100}=5 \text{ per cent.}$$

Then multiply the determined per cent. of slip by the number of tons of coal burned per year, and then by the cost of the coal per ton. Thus we have

(2,000 x $9 x .08= $1,440.)

the yearly cost of belt slip.

To arrive at the actual and accurate cost of belt slip is not easy, however. It is plainly more than $1,440 in such a plant as above, because coal is not the only thing that is lost. The belts wear out more rapidly where there is slip than where there is no slip, and the cost of this slip can be approximated.

Let us assume, just for an example that with cork inserts a plant manages to keep its belts a-going for 10 years. The first cost, then, is $500 per year. Without cork inserts the belts wear out in eight years, and the average cost is $625 per year. This would mean a saving of $625—$500, or $1,250 in 10 years. As these figures may not apply to every plant this formula may be used and the reader can substitute his own conditions.

Dollars saved with cork inserts from belt cost standpoint only equal

$$\frac{(Nc - N)\ K}{N}$$

where Nc=life of belt in years with cork inserts;

N=life of belt in years without cork inserts;

K=first cost of belt in dollars.

The cost of lost product must also be considered. The value of cork inserts appears here again, and the problem can be approximated mathematically. Let us take, for example, the above plant where over-all belt slip is 8 per cent. and where the output should be worth, without slip, $2,000 per day. With 8 per cent. slip it is evident that the machines are running 8 per cent. too slow and the product is, therefore, diminished by 8 per cent. Hence the daily output is approximately $2,000—($2,000 x 8%)=$1,840 . instead of $2,000.

To make the formula clearer, and to enforce this cost on the mind of the plant owner, I have thrown it into this form:

Dollars output lost per day=

$$\frac{D}{1-S}-D$$

were D=present daily output in dollars;

S=per cent of belt slip.

Thus, if your present daily output amounts to $1,500, and if your over-all belt slip is 10 per cent, we have, after substituting in the formula

$$\frac{1,500}{1-.10} - \$1,500=\$1,667-\$1,500=\$167.$$

One hundred and sixty-seven dollars lost per day is considerable and may mean the ruin of a small plant, unless discovered and rectified. This "product loss" is often saved by speeding up the driving engines or motors to the extent that after belt slip is deducted the final speed is what it should be anyway. That method is better than none at all, but it is not the best practice. The best practice is to eliminate all belt slip.

Thus comes the cost of defective product. Where belt slip is permitted, the product frequently suffers on that account. The loss cannot be figured mathematically, because it is too uncertain. It may vary from a trifling to a very serious amount. To reduce this loss to the minimum, belt slip must be completely eliminated. By so doing, all machines are driven by steady speeds. There is no bunching here and thinning there. Product is uniform, day in and day out. Such is the ideal state as regards speed, and the value of cork inserts is further emphasized.

A REMARKABLE EXPLOSION

It is often possible, after a boiler explosion, to discover the cause or causes of the accident, says the "Traveler's Standard," but sometimes it is next to impossible to determine why certain boilers do not explode. Inspectors often discover boiler installations that are marvels of ingenuity in certain ways, although the persons who set up the boilers and connected them apparently stopped work upon reaching the stage where it was possible to raise steam, and entirely overlooked the exceedingly essential element of safety. A unique outfit of this kind, which was reported to us recently by one of our engineers who found it while inspecting an elevator on the premises, was bad enough to merit description.

The boiler in this case is a small one of the vertical type (being only 12 inches in diameter and 20 inches long) and is used to supply steam for a hat-cleaning and shoe-polishing establishment on the floor above. It is installed in a basement and is mounted on two wall brackets. Heat for generating steam is supplied to it by means of a large gas burner which is connected to the gas main on the first floor by flexible tubing. The gas shut-off cock is located on the first floor of the building, and is opened to its fullest extent when steam is required, at other times the cock is partly closed, but the gas is supposed to be kept burning constantly during working hours.

The usual method of operating the boiler is as follows: The first thing in the morning, two or three gallons of water are put into the boiler through a branch pipe connected to the main steam line—this branch pipe being equipped with a funnel and a stop valve. After the water has been introduced, the stop valve in the branch pipe is closed, gas is turned on by opening the gas cock on the first floor, and the gas is then lighted at the burner in the basement and left burning with the cock wide open until a steam pressure of from 20 to 25 pounds has been raised. The gas cock is partly closed when no steam is needed, as previously stated.

An examination of the boiler and its fittings showed them to be in a sorry state. The vertical seam of the boiler was leaking badly, but that was a comparatively minor trouble, and perhaps it was a real advantage, inasmuch as it afforded a means by which the boiler could relieve itself to some extent, in case the pressure got too high.

A gauge glass had been provided, but it was so choked with dirt that it could give no indication of the water level in the boiler, and in fact it resembled an iron rod more nearly than it did a gage glass. A spring safety-valve was also mounted on the top of the boiler, but a brick had been wedged between it and the basement ceiling so that it could not possibly operate. The brick was removed, but even then the inspector found it almost impossible to raise the valve. The history of the brick is not recorded, but it can be supplied, with a fair measure of probability, by conjecture based upon a knowledge of how such things go. It is likely that the safety-valve blew off at some time or other in the more or less remote past, and liberated so much steam and water that the flame at the gas-burner was put out. Somebody who happened to be near by detected the odor of escaping gas, and attended to things before any serious result occurred. The brick (as we read the story) was then introduced to prevent subsequent annoyance of this kind—and it certainly was effective.

The proprietor of the hat-cleaning establishment on the first floor was asked how he knew when water was needed in the boiler—the gage glass being entirely useless. He replied that when he opened the valve to obtain steam for cleaning hats, he could tell by the odor whether the steam was dry or not. If it was wet, he knew there was some

(Continued on page 50)

"Tout Passe"

(Everything Changes)

THE FRENCH have a proverb which begins "*Tout passe*" (Everything changes). This contains the germ of an idea which should be good medicine for the business man who is inclined at the present time when trade is quiet to rest on his oars and delay making preparations for the busy period until that period actually arrives.

Everything in this world is continually changing. Some philosophers even tell us that there is no present; there is only the past and the future; the past is gone and to-morrow, even the next hour, the next minute, are in the future. And in the future only one thing is certain, that is, change.

So conservative is human nature that the great majority instinctively assume that whatever conditions exist at the moment must continue to exist for some time to come. The direct contrary is, of course, the case. The philosopher knows that whatever else may happen one thing is certain, viz., whatever is, is not going to continue.

Why is it that only the few can make money in stock exchange speculation? Because the ordinary man waits until prosperous times appear to him to have become established and to have become a permanent institution before he buys. And in most cases he then finds he has bought at the top of the market. On the other hand, when things are at their lowest and he could buy with a prospect or almost a certainty of profit, everything appears to him black and he cannot see any likelihood of change. The shrewd operator, however, knows that when things look at their worst it is time for them to mend. This is the time he chooses for buying and when everything is booming is the time he picks for selling.

We may not be on the eve of a big boom, but one thing is certain, things are not going to remain as they are for long.

Now is the time when shrewd and far-seeing men are preparing for prosperous times. They are making preparations so that opportunity may not take them unawares. They see that now is the time to cultivate trade and make their products known so that when the tide of prosperity is on the flow they may be in a position to take advantage of it and reap the benefit of their foresight.

If anyone tells you we are in for several years of business depression, take heart and be assured that this is a sign we must be nearing better times.

In the spring of 1918 many well-informed men predicted three further years of war. The war ended that autumn.

In 1920 many business men spoke of three or four more years of prosperity. The prosperity wave was even then on its ebb.

These men like the great majority did not realize that everything changes. Are you going to place yourselves among their number, or are you going to rank among the minority and bear in mind the proverb—*Tout passe?*

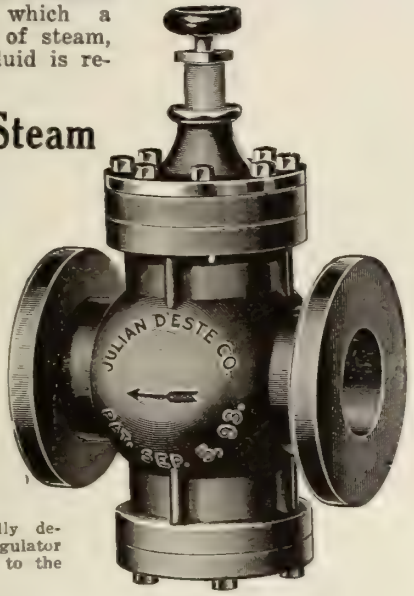
CURTIS Engineering Specialties

Universality!

For universal application to all the varied and various conditions under which a reduced pressure of steam, water or other fluid is required the

Improved Steam Pressure Regulator



has no equal.
It is compact and self-contained, without levers, weights or projections.
No glands or packing; no drip for leak of steam or water. Suitable for any boiler pressure; made entirely of metal; is a lock valve, very simple and sensitive.
Send for leaflet fully descriptive of this Regulator (contains price list) to the manufacturers.

Canadian funds are accepted at par at Montreal.

A Slice Bar *and* PLIBRICO

JOINTLESS FURNACE LINING

That's all you need when a fire brick falls out of your furnace lining. The **PLIBRICO** will plug the hole satisfactorily until you are ready to put in a new lining. Then make it of **PLIBRICO** and **avoid future trouble.**

PLIBRICO'S hard, smooth, jointless walls offer no place for disintegration to start; they are air tight and gas tight, they resist heat up to 3100° F., and they outlast laid-up fire brick from two to four times.

A complete **PLIBRICO** setting—baffles, side and bridge walls, front and back arches—is a big-paying investment.

PLIBRICO is delivered only in steel containers of distinctive appearance as shown below.

Send for our catalogue L-52 on "Modern Furnace Building," and ask to have our nearest representative call.

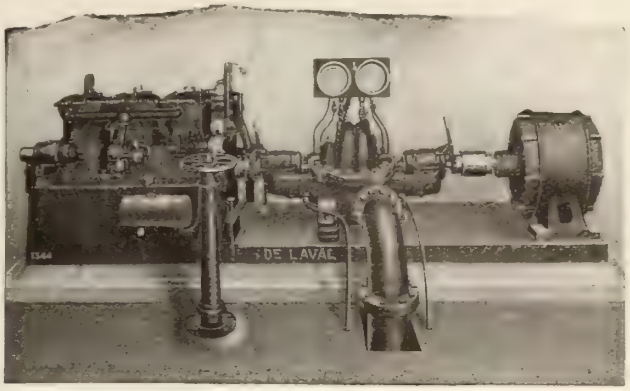
1142 CLAY ST., CHICAGO, ILL.



LINDSAY, ONT., SURE OF WATER SUPPLY

THE accompanying photograph shows a combined electric motor and gasoline engine drive for a De Laval two stage centrifugal pump installed by the city of Lindsay, Ont. This unit is guaranteed to deliver 1,325 gal. per min. against 290 ft. head.

The dual drive makes it possible to take advantage of the comparatively low cost of electrical power, with a further saving in attendance charges, and at the same time to have absolute insurance of water supply in case the electric supply should fail. The pump can be connected to either source of power by means of the clutch coupling shown. The De Laval centrifugal pump is simple and reliable. There are no water valves or plunger or piston packings. All working parts are accessible upon lifting the casing cover and can be removed after taking off the bearing caps. Parts subject to wear, such as shaft protecting sleeves, wearing rings and impellers, are made to limit gages on an interchangeable basis, and can be quickly and easily exchanged by ordinary unskilled men.

State your pumping requirements and ask for our special publication B100.

water in the boiler, though he could not tell how much.

Here was a boiler being operated practically without any safety devices—the gage glass choked with dirt, the safety-valve inoperative, and the boiler unattended except at infrequent intervals and in the most casual manner. Yet it did not explode, although other boilers did, elsewhere, notwithstanding the fact that they had been provided with every known safety device, and had received constant and intelligent care. The why of a situation like that is a mystery beyond human ken.

In this case, in addition to the danger of a boiler explosion, the possibility of a gas explosion is ever present, because the boiler is gas-fired and is out of sight of anyone interested in the operation or use of it. The gas flame, when turned low, might be blown out by a current of air, and thereafter the gas would escape into the basement until, if not detected, it would accumulate to such an extent that the stage would be set for a disastrous explosion. An electric motor is installed near by, and the gas might easily be ignited by a spark from this, or by any open flame that it might reach.

On the recommendation of our inspector, the gage glass was cleaned out and the safety-valve was overhauled and set to blow off at a pressure of 25 pounds. He also recommended that the boiler be provided with a proper device for supplying feed water, and that it be removed from the basement and placed in the hat-cleaning establishment, where it could be under constant supervision.

OFFSET SCREW DRIVER

Machine screws that have screw-driver slots in them often present a rather awkward problem when it is desired to screw in or remove them, owing to the location of the screws close to a wall or other projections. To overcome such conditions an offset screw-driver has been designed. Each screw-driver consists of a handle having a square forged end. On the four sides of this squared end are long narrow projections with which the slots of screw heads may be engaged. When using the screw-driver the handle is held at right angles to the axis of the screw. The projection that engages the screw-driver slot on any one side is at an angle of 45 degrees to the projection on each of its adjacent sides. Therefore if a screw is located in a cramped position, after turning the screw as far as space will permit, the screw-driver is given a quarter turn about its own handle axis by the fingers and is again applied. The screw-driver will put in or withdraw screws if only a one-eighth turn is possible. The design also has the added advantage that a considerable leverage can be applied to the screw if necessary. The manufacturers of the offset screw-driver are the Porter Products Corporation of Syracuse, N. Y.

Toronto University is planning the erection of four new buildings and a requisition has been forwarded to the Provincial Government. The plans include a new Forestry building, botany, and Administration buildings, a Woman's building, and additions to the heating plants.

BOOK REVIEW

The "Coal Manual" is the title of a book issued by the National Coal Mining News, Cincinnati, which deals with coal from all the aspects which are of use to a purchaser and user of this universal fuel. In addition to chapters on the analysis of coal, other chapters deal with the efficient burning of coal, and there are instructions to firemen and engineers. The book, which is published at $2.50 in the U. S., should be a valuable one for purchasing agents, plant managers, and engineers in general.

The Victoria Machinery Depot, Victoria, B. C., has been awarded the contract for repair work to the Canadian Pacific car ferry No. 8, driven ashore last month at Porlier Pass and later salvaged by the Canadian Salvage Company. The figure is understood to be in the neighborhood of $50,000. The same firm also has the contract for the overhauling of the C. G. S. Newington, the lighthouse tender operated by the Prince Rupert Agency of Marine. A new tail shaft will also be fitted to the steamer. The Newington is now southbound and expected in a few days at the Upper Harbor yard.

A sliding scale rate which will run from sixty-fie to eighty ents per hour instead of a flat rate basis which is now in effect, will probably be offered to members of the electricians' union of the city. Under the present agreement which expires May 1 the men received 80 cents an hour.

MAKE YOUR ROOF STORM-TIGHT

REED'S Roofing Cements—either **"Plastic"** or **"Liquid,"** will make your old roof as good as new. These Roofing Cements are built on a heavy bituminous base, impregnated with long asbestos fiber and other ingredients. They are tough, waterproof and elastic. Easy to apply. Put up in one, five and ten pound tins, and in 100 lb. kegs, half barrels and barrels.

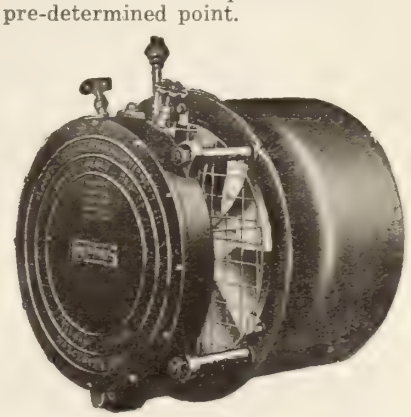
Robert Crean Co., Toronto.
Canada Foundries & Forgings, Welland and Brockville.

THE Coppus Turbo Undergrate Blower is a small, compact, forced draft unit consisting of a steam turbine with an aluminum air propeller mounted in a special double ball bearing support, and arranged with an expanded cast iron outlet.

The blower is generally located in the front or side wall of the boiler setting. When the blower starts it forces a current of air under the grates, creating forced draft. This draft can be automatically controlled if desired, so that when the pressure on the boiler drops, the blower will automatically start and continue to operate until the pressure is built up to a certain pre-determined point.

COPPUS BLOWERS are built with interchangeable parts. Bearings and oiling system are so designed that they are not affected by dirt or grit. The expanded outlet casing reduces the resistance at the point of discharge, and greatly increases the fan capacity.



We will be glad to send you copies of bulletins

LUNKENHEIMER CAST STEEL "VICTOR" GATE VALVES

ELECTRICALLY OPERATED

Provides for remote control and the quick closing of the valve in case of an emergency such as may arise should a break occur in one of the steam lines. Also eliminates manual operation which in the larger sizes of valves is an arduous task and consumes considerable time.

Procurable in sizes 6 inches and larger. Equipped with the well known Dean Motor and Control system which permits of as many control stations as desired.

There are many noteworthy features about Lunkenheimer Electrically Operated Gate Valves that merit consideration.

Detailed specifications will be sent to those interested.

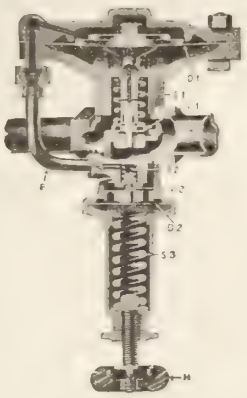
FISHER
TRADE MARK REGISTERED



You Are The Loser

Unguarded steam disappears. It has no value. Once gone, it is gone forever.

AND YOU ARE THE LOSER

Fisher
Pressure Regulator
(Series 90)

will watch your steam. It will release exactly the desired amount of reduced pressure—and no more.

It is especially valuable in curing, drying, bleaching, dyeing, vulcanizing, evaporating and any other process dependent upon a uniform temperature or pressure.

It shuts off absolutely all supply of steam when the process it is serving is suspended.

Actual service in thousands of plants throughout Canada has proven Fisher Power Plant Specialties to be long-lasting and accurate in the most trying and delicate operations.

Ask your dealer or jobber for full information about the Fisher line. Or write for "POWER PLANT SPECIALTIES." It is full of valuable information.

Agencies in all principal cities

Four Reasons

Why Manufacturers Choose the MacLean Technical Newspapers to Carry Their Message to the Buyer

1. Technical Newspaper, with special stress on the syllable **news,** is the correct term to apply to any of the publications of the MacLean Technical group. Each issue of Canadian Machinery, Canadian Foundryman, Power House and Marine Engineering represent the work of a widely experienced editorial staff—a staff of practical men who are well versed in present-day requirements. They keep the employer and his workroom executives in close touch with the latest ideas in industrial practice and at the same time give them interesting news of the trade. Workmen with an ambition to advance find the MacLean technical newspapers a sure means of success. The papers serve a broad field and serve it thoroughly.

2. By subjection to the rigid test of an audit by the Audit Bureau of Circulations, each of the MacLean Technical Papers not only proves its circulation but tells definitely just what kind of people it reaches. Such being the case, specimen copies, "bulk" subscriptions and subscriptions long in arrears are not taken into consideration. The paper with a high aim and nothing to conceal is invariably connected with the A. B. C.

3. Enrollment in the Canadian National Newspapers and Periodicals Association is another instance of progress and square dealing. It demands the following pledges:

"To consider first the interests of the subscriber."

"To work for truth and honesty in all departments, and among other things to supply advertisers with full information regarding character and extent of circulation."

4. Rigid adherence to the practice of progress, service and fair dealing has resulted in the MacLean Publishing Co. becoming the largest disseminators of technical information and trade news in the British Empire. To-day the Company publishes, all told, sixteen technical and trade newspapers and magazines, and besides the immense office of publication at Toronto, offices are maintained at Montreal, Winnipeg, Vancouver, Chicago, Boston, Cleveland, New York, and London, Eng.

Bailey Meters
Show the Leaks

There is nothing more wasteful than the old flat rate basis or estimated charges for steam. It has many leaks, and occasions the loss of thousands of dollars in many Canadian manufacturing plants. The leaks and much unnecessary use of steam will be quickly stopped by the adoption of Bailey Fluid Meters. A Bailey System of Meters will give you the **complete heat balance** of your plant. With this knowledge you can turn losses into power. Bailey Meters record the rate of steam flow, pressure and temperature with absolute accuracy.

May we tell you exactly what Bailey Meters will accomplish in your plant?

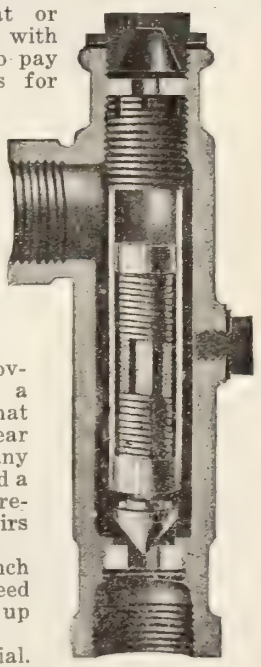
Made in Canada

A New SARCO costs Less than to Repair Other Traps

THE numerous parts in both float and bucket traps wear out — are constantly needing repairs, replacement and adjustment. For example, the float. To put in a new float alone costs around $12.00, besides the labor. And the cost of other new parts is often almost as high.
Now consider this fact—in all sizes under one inch, you can buy a complete and brand new Steam Trap Sarco for considerably less than $12.00, and larger sizes for only a little more.

STEAM TRAP
SARCO



Nine times out of ten it is cheaper to scrap a float or bucket trap and replace it with a brand new Sarco than to pay for repairs or new parts for the old trap.
It is less bother, too. A new Sarco can be installed without any building up, without any platform or support of any kind. And the Sarco takes far less room—fits in like an elbow, at any point in the line and at any angle, without any change in the piping.
Because it has only one moving part—and that with a simple and direct action that practically eliminates wear —a Sarco will outlast any other trap ever made. And a Sarco practically never requires adjustment or repairs or attention of any kind.
Made in sizes from ⅜ inch to 3 inches, and guaranteed for any given pressure up to 200 lb.
Sold on 30 days' free trial.
Send for Booklet J-24.

HINTS TO BUYERS

Kingsbury Thrust Bearings

Made in Canada

Our pivoted-block Thrust Bearings are a complete solution of all thrust-bearing problems in hydro-electric units, steam turbines, ships' propeller shafts, centrifugal pumps, and similar work involving heavy loads and high or low speed.

Maximum Durability and Reliability.
Lowest possible Friction.
No limit to loads or speeds.
Protected by numerous Canadian Patents. Complete manufacturing facilities in Canada, insuring prompt deliveries and service.

Send for Catalogue.

Slightly Used POWERPLANT EQUIPMENT

Dependable —and Cheap

We have on hand at all times a large variety of equipment—some slightly used but practically as good as new—at prices that, positively, can not be duplicated anywhere.

We handle only high grade products that are backed by makers, ourselves and users.

Compare our values on Vertical, Horizontal, and Firebox Boilers; Marine Internal Fired Automatic Engines; also Vertical and Horizontal Engines.

Right now, some excellent values may be obtained by quick action.

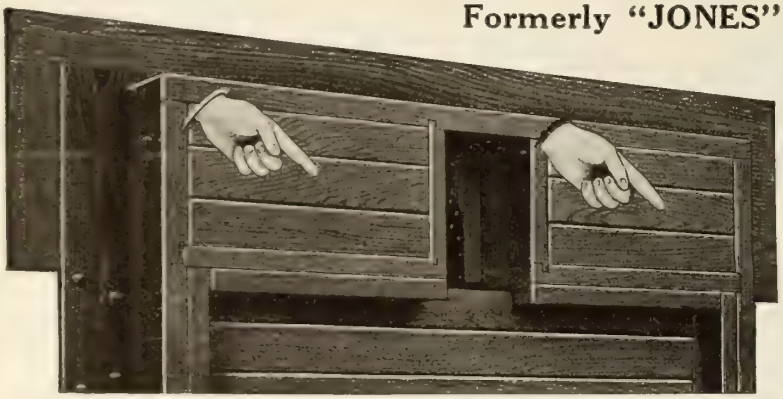
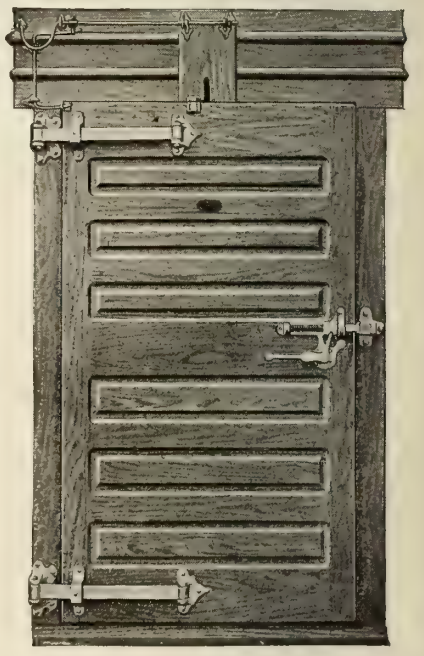
Incomparable JAMISON

Formerly "JONES"

Heavy Duty Cold Storage Doors





Have Many Points of Superior Construction

Note the back of our Standard Track Head Frame with track part; we insulate and finish our track frame heads, an unusual feature. Then note the simplicity of the Track Lift device over the door; no springs or other delicate parts to get out of order. Our Automatic Self-tightening Fastener draws the door rigidly tight each time it is slammed. The hinges too are three to five times heavier than other makes.

These features, and many others, are fully explained in catalog No. 10. Write for it.

P&H FLANGED PIPE JOINTS

SCREWED

P.H. LAP

P&H LAP FLANGES, for any service, have proven to be the best yet designed, and they have many advantages over other styles. The pipe is not weakened by cutting into the wall as when using screwed flanges. The gasket bears on the face of the lap and absolutely prevents leakage through the bore of the flange. The hub of the flange is bored slightly larger than the outside diameter of the pipe so that the flange will swivel readily and accommodate itself to any slight variation in the position of the bolt holes, an advantage which is obvious to the fitter and eliminates torsional strains in attaching.

Sole Manufacturers of the celebrated "MAPLE LEAF" Brand Stitched Cotton Duck Belting and Belt Dressing.

The demand for our products has steadily increased because the standard of quality has been maintained.

We make only one grade, the best that can be produced.

"MAPLE LEAF" is the strongest, truest running, most economical and efficient belt on the market for transmission of power, conveying, etc.

Being thoroughly waterproof it is suitable for running in wet or dry places. **"MAPLE LEAF"** Belt Dressing is different to others offered in that it is equally good for all kinds of belting, leather, rubber, or Balata, as well as our own make.

Write us for prices, and if desired we will be pleased to furnish samples and further information.

A trial order will convince you of their utility.

"SPECIAL"

Reliable
At All Speeds

This outside-packed Ram pump has many distinguishing features and embodies all the improvements suggested during many years of practical experience.

A special feature of this pump is its adaptability to work that is variable. It will run at very slow, as well as at normal speed, with absolute reliability and maintain a full stroke under all circumstances. Experience has shown that the outside packed Ram Pump is the only one suitable for pressures of 100 pounds and upwards.

We also make Vertical Engines, Winches, Cranes, Castings, Forgings, etc.

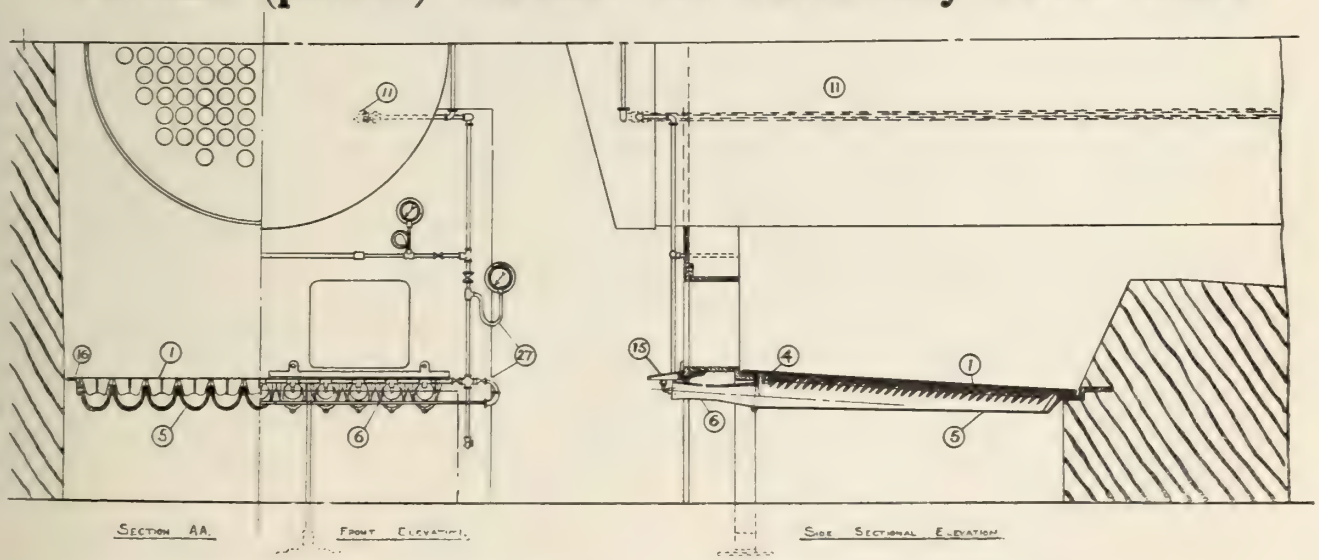
Turbine (patent) Furnace for Externally Fired Boiler



1. Removable fire bars.
4. Locking bar.
5. Air trough.
5. Air injector.
11. Superheater.
15. Ash guard.
16. Side extension.
27. Steam fittings.

Will Maintain Highest Production on Cheap Low Grade Fuel

This is not mere assertion but a claim backed by the experience of over 1,000 British Plant Owners. Wherever it is installed it is recognized as the highest form of fuel economy. **Write us.**

Manufactured by: The Turbine Furnace Company, Limited, London, England

Sole Canadian Agent: PERCY A. GOEPEL, 525 Pender St. W., VANCOUVER

For Handling Both Coal and Ashes

The Peck Carrier Means Economy and Reliability

ONE sturdy reliable unit, instead of several inferior machines for accomplishing the same results.

Handles both coal and ashes with less upkeep than required for individual machines for coal and ashes.

Costs practically the same as elevators, conveyors, skip hoists and other equipment required to do same work—and is more dependable.

Operation and maintenance is less than for any other types of coal and ashes handling apparatus.

Minimum power required, the equipment runs slowly, is noiseless, and is always ready for service.

Back of the Peck Carrier stands the reputation of this Company—with hundreds of successful installations.

We also make:

Track Hoppers
Coal Crushers
Coal Bunkers
Weigh Larries
Gates and Chutes
Drag Scrapers
Skip Hoists
Portable Conveyors
Traveling Water Screens
Locomotive Cranes
Electric Hoists

Write for Catalog No. 220, describing many installations and giving names of users.

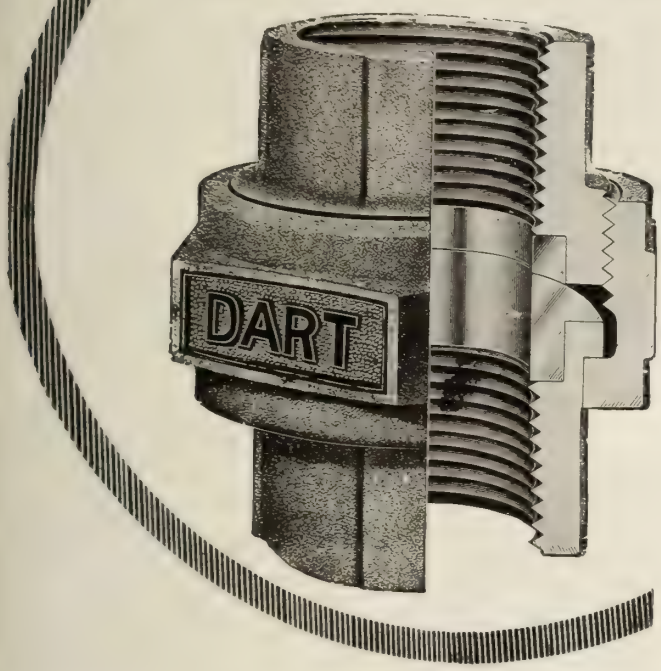
DART Union Pipe Coupling

The kind that leaves no room for complaints and saves time



Never Loosens Never Leaks

BRONZE MEETS BRONZE AT THE JOINT

Use Dart Unions—they make a joint that stays tight permanently. Your customers will never be bothered with leaks.

Make sure your next Jobbers' order includes Dart Unions

Manufactured by

Dart Union Co., Limited, Toronto

The Safe and Certain Boiler Cleanser

PUT a barrel of BOICO in your boiler room. It's the most efficient and economical **clean-boiler insurance** you can adopt. BOICO routs the most stubborn cases of boiler scale formations quickly and thoroughly.

Hundreds of Plants are Using BOICO Every Day With Unqualified Success

What BOICO will do in one plant it will do in another—**it will do in yours.** BOICO loosens and brings away the hardest of old formations and keeps new scale from gathering. Yet it never does the slightest injury to boilers, valves or packings. Neither does it carry over in the steam, nor cause foaming or priming.

We are confident that BOICO will live up to all our claims and are prepared to let you test it FREE of cost. You have nothing to lose by trying it—let us hear from you.

Anti-Clinker Shell Bar Grates

There's no coal waste where these grates are used. Maximum air-space provides for perfect combustion. No clinker formation here, and you get more heat with less fuel.

One-Piece Jointless Furnace Lining

Why shift the blame on your engineer or fireman when it is your furnaces that are not up to the highest point of efficiency? USE PLIBRICO—it lasts longer than fire brick and is easier to instal.

Tip-It Patent Welding Process

With TIP-IT you get tools with shanks of carbon and tips of high-speed steel.

Better Business— and Superheat

Better business calls for more than an increased volume of sales; better business means greater profits.

Greater profits and better business demand lower operating costs or a higher return on every dollar invested in power plant equipment.

And not the least important reduction you can make is your fuel cost, and lower fuel bills will mean

ELESCO SUPERHEATERS

Now that you are thinking of better business, and as better business is waiting for you, send for our Bulletin NT-7 "What Every Executive Should Know About Superheated Steam."

THE SUPERHEATER COMPANY, LIMITED

Transportation Building, Montreal

WORKS AT SHERBROOKE, QUEBEC

Western Representatives: The Taylor Engr. Co., Ltd., Vancouver, B.C.

Designing Engineers and Manufacturers of ELESCO Steam Superheaters and Pipe Coils for all purposes; Feed Water Heating Equipment for Locomotives; Boiler Feed Pumps for all services.

MADE IN CANADA

AEROPLANE VIEW OF LOWER NEW YORK

The Financial Center of the World Indorses Venturi Meters

The sky-line of lower New York is as varied as the uses of the Venturi Meter. In the area shown in the photograph, are installed more than 100 VENTURI METERS. Manhattan Island has in daily service over 400 VENTURI METERS.

These Venturis measure not only cold and hot water, but steam, air, gases, oil, brine, sewage, anhydrous ammonia, chemical solutions and quicksilver.

The use of VENTURI METERS for measuring all liquids and gases has become standard practice where accuracy, low maintenance cost and reliability are desired at a reasonable first cost.

OUR EXPERIENCE IN FLOW MEASUREMENT IS AT YOUR DISPOSAL

Mechanical Goods of Proved Value

The right machine or supplies for your particular requirements; experienced men who can give you definite information regarding your special problems—both may be found at the nearest branch of Canadian Fairbanks-Morse.

Fairbanks-Morse products, designed by our own engineers and made in our own factories, have built up a world-wide reputation for reliability.

Canadian Fairbanks-Morse agencies comprise the world's leading manufacturers of mechanical goods—of machines and supplies that have the fullest endorsement of the largest number of users.

Here are some of the well-known lines we handle:

Fairbanks Scales
Pratt & Cady Valves
Palmetto Packing
Strong Steam Traps
Allen Engines
Landis Threaders
Graton & Knight Leather Belting
Yale Chain Hoists
Gould's Pumps
Fairbanks Valves
Durabla Packing
Foster Regulators
Fairbanks-Morse Gas and Oil Engines
South Bend Lathes
Dick's Balata Belting
Norton Grinding Wheels
Fairbanks-Morse Generators
Fairbanks-Morse Pumps

Each department is ready to extend the fullest co-operation in the solution of your problems because it is in charge of experienced men who know how best to meet your particular requirements.

MORRISON

STEAM GOODS

Steam Fan Regulators

THE application of a close study into the requirements of steam specialties during our fifty years' experience is reflected in the widespread popularity of Morrison Steam Goods.

Exacting engineers appreciate the fact that superior quality, workmanship and design ensures dependability at all times, even under the shocks of constantly changing conditions.

The Regulator here shown may be depended upon to maintain a uniform boiler pressure by varying the speed of the Fan Engine according to the requirements of the plant. They are also used for controlling steam jet blowers.

Files Hand Stokers Getting Results

PANTHER RUBBER COMPANY, LIMITED

GENERAL OFFICES AND FACTORIES
SHERBROOKE, QUE.

SHERBROOKE, CANADA September 23, 1921.

The Waterous Engine Works Co. Ltd.,
Brantford, Ont.

Gentlemen:

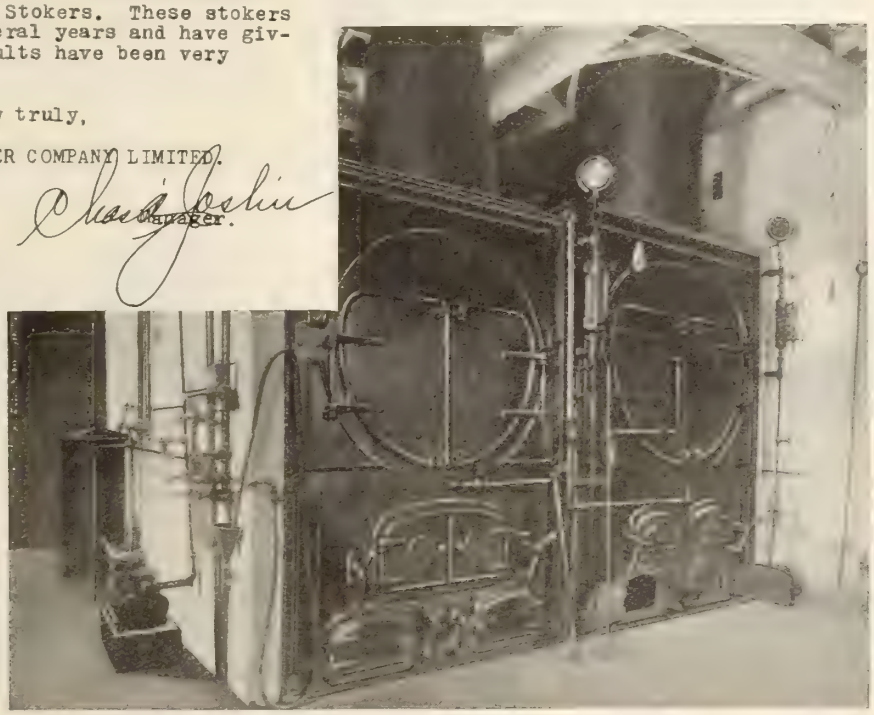
In reply to your letter of the 8th instant we have in our plant the Files Stokers. These stokers have been in operation for several years and have given excellent service. The results have been very satisfactory.

Yours very truly,

PANTHER RUBBER COMPANY LIMITED.

Manager.

CAJ/RMK



It is the uniform excellent service and general satisfaction that have caused progressive men to select **Files Stokers.** These are typical of the more complete data we have compiled:

One installation (3,600 H.P.) saved enough coal to pay for their stoker investment in five months.

A Files installation operated for five months continuously at an average rating of 223%—doubling their steam output.

Files stokers increased efficiency of one plant sufficiently high to warrant discontinuance of two out of eight boilers.

Here is a ready explanation of these achievements:—

1. **Complete volatilization of green coal, causing intensified combustion and smoke dissemination.**
2. **Correct distribution and proper proportion of air according to load carried**
3. **Fuel bed continuously kept clean, uniform and rich.**

Given the opportunity we will be glad to present these facts for your complete satisfaction.

New Truths and Old Fallacies

THERMAL CONDUCTIVITY

The value of a metal for babbitt purposes is also indicated by its thermal conductivity, as shown by the following figures, starting with silver as a basis of comparison because it has the highest conductivity:

Metal	Thermal Conductivity
Silver	0.993
Copper	0.924
Zinc	0.269
Tin	0.155
Lead	0.084
Antimony	0.024

The appropriateness of the e figures is that an alloy composed of metals of low heat conductivity is relatively slow in accumulating heat. It is well known that bronze and brass mixtures heat quicker than tin mixtures, and the latter in turn heat quicker than lead mixtures. The vibratory quality of resonant metals doubtless has much to do in promoting and accelerating heat production.

Rapid heating has a tendency to loosen the lining in shell and even to cause it to come unsoldered sometimes.

Magnolia is not our only product. If you must have some Genuine, we make Adamant Armature, or if you insist upon a cheaper metal than Magnolia, we make Defender, Mystic and Kosmic Brands; also No. 4 and other hardware grades.

A babbitt ingot is not an object to excite interest or admiration; it is accounted as among the humblest of engine room supplies, yet it has been the subject of much learned investigation in its development and also in its daily production, and not a railroad, steamship or factory could be operated without it, and even human life is sometimes dependent upon it.

We could tell many a tale of human interest concerning Magnolia and its valiant work in hours of need and peril, but it is near closing down time and we must bring this article to an early conclusion.

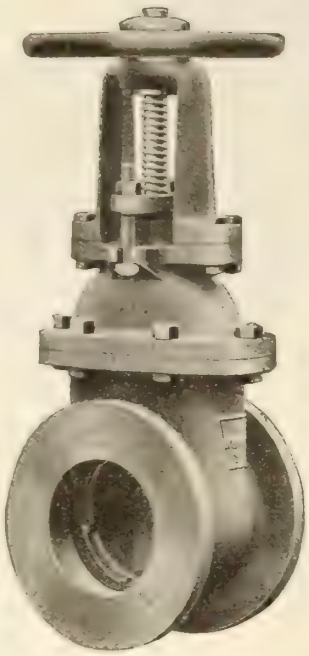
KERR (Keystone)
Iron Body Gate Valves



Strength and Compactness Here

FOR over forty years we have made a particular study of valve requirements, improving the designs of our products to conform with modern advancement.

This policy, together with the exercise of the greatest care in design and manufacture, is the factor behind the constant repeat orders we receive.

We honestly believe that our new style patterns of valves (notably Iron Body Gate and Swing Check Valves) represent as high a degree of perfection as it is possible to attain.

All KERR products are subjected to severe testing before they leave our works and when you purchase KERR products, a KERR guarantee backs the sale.

May we send you a catalogue?

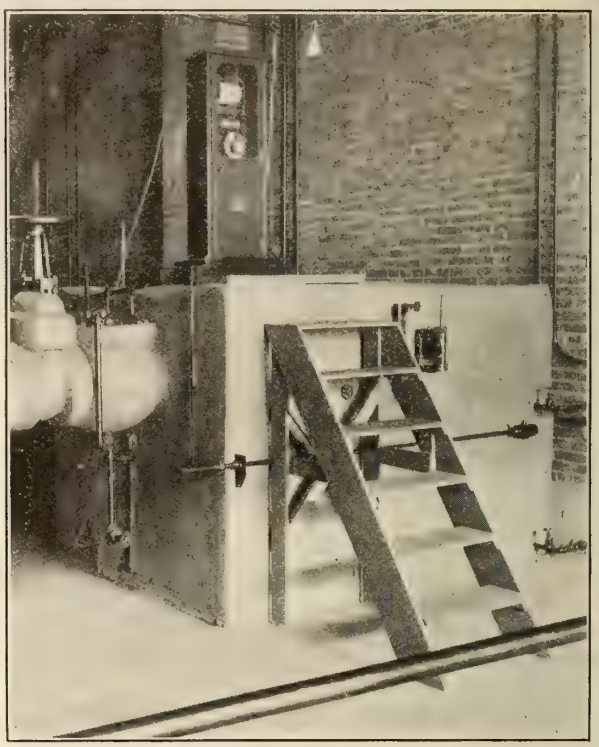
No Guessing Here

This concern KNOWS how many pounds of steam are produced by each pound of coal burned.



Yarway-Lea V-Notch Meter of 400,000 lbs. per hour capacity with temperature recorder, at Utilities Construction Company, Lorain, O.

THE boiler room offers greater opportunities to effect substantial economies and increase efficiency at small cost than any other part of the average plant. More and more executives are coming to realize the prime necessity of **knowing** what results are being obtained—of having some accurate means of checking up on the actual accomplishments. And many of the most progressive are installing YARWAY-LEA V-NOTCH METERS, thereby getting black-and-white records of boiler room operation by correct and dependable measurement.

Among the 2,000 and more modern plants equipped with YARWAY-LEA V-NOTCH METERS is that of the Utilities Construction Company at Lorain, Ohio. They use an extra storage type meter of 400,000 lbs. per hour capacity, in conjunction with an open heater, to measure boiler feed water. A recording thermometer, writing on same chart, gives temperature of water being measured.

Bulletin L-40 contains boiler room information of value to you. We shall be glad to forward a copy at your request.

The YORK

VERTICAL SEMI-ENCLOSED HIGH SPEED MACHINE

DIRECT CONNECTED TO UNIFLOW ENGINE

PRODUCTIVE cost per ton of refrigeration in a steam driven plant depends, to a large extent, on fuel consumption, which in turn is affected by steam economy. To obtain the best economy in any steam engine, four principal requirements are necessary—High Steam Pressure, High Superheat, High Vacuum and High Speed.

The York Uniflow Engine, in actual service, has met these requirements most satisfactorily. It is a very economical unit—low in steam consumption under the variable operating conditions encountered in ice making and refrigerating plants, and absolutely reliable under the most extreme of these conditions.

The great range of speed possible with this engine, makes it well adapted for direct connection to York High Speed Refrigerating Machines.

Consult our nearest Branch. It is fully equipped to render prompt service.

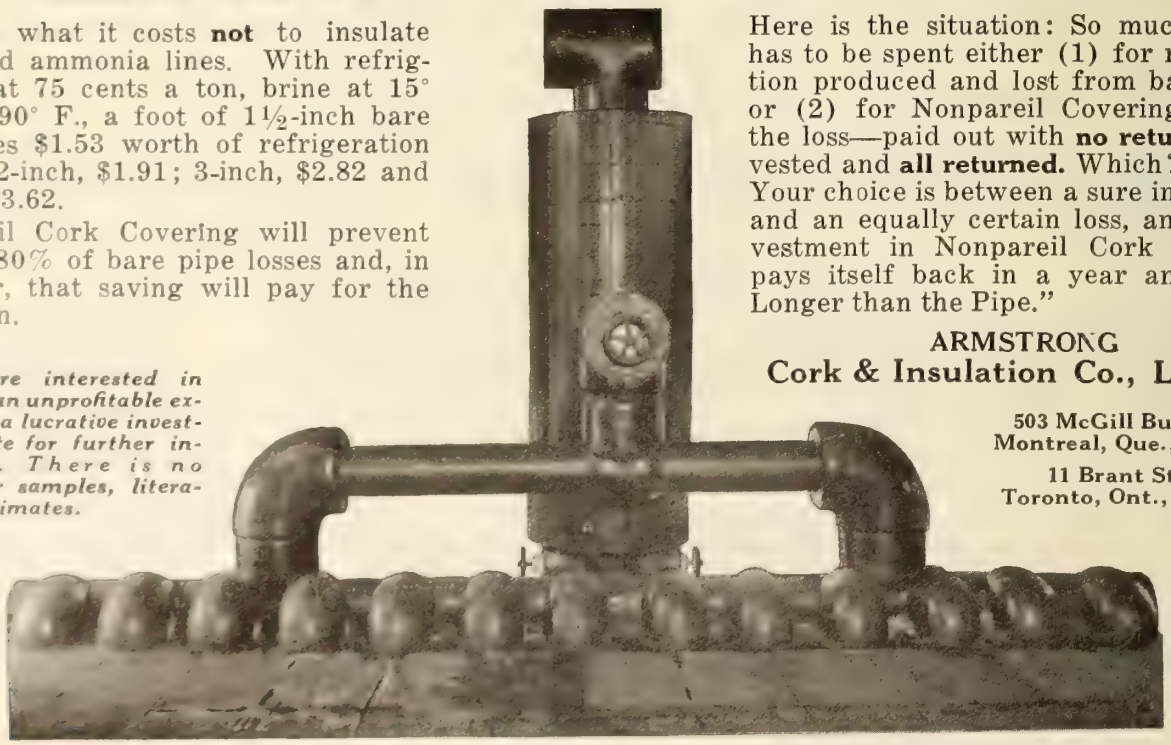
JAMISON COLD STORAGE DOOR CO.
(Formerly Jones Cold Store Co.)
HAGERSTOWN - MARYLAND, U.S.A.

GETTING AT IT BACKWARD

Let's see what it costs **not** to insulate brine and ammonia lines. With refrigeration at 75 cents a ton, brine at 15° and air 90° F., a foot of 1½-inch bare pipe loses $1.53 worth of refrigeration a year; 2-inch, $1.91; 3-inch, $2.82 and 4-inch, $3.62.

Nonpareil Cork Covering will prevent at least 80% of bare pipe losses and, in one year, that saving will pay for the insulation.

If you are interested in changing an unprofitable expense into a lucrative investment, write for further information. There is no charge for samples, literature or estimates.



Here is the situation: So much money has to be spent either (1) for refrigeration produced and lost from bare lines; or (2) for Nonpareil Covering to stop the loss—paid out with **no return,** or invested and **all returned.** Which?
Your choice is between a sure investment and an equally certain loss, and the investment in Nonpareil Cork Covering pays itself back in a year and "Lasts Longer than the Pipe."

Johns-Manville Anti-Sweat Insulation

A dripping sweat —and the remedy

WE do not always realize the extent of the damage to stored merchandise and goods in process, caused by the sloppy, unsanitary drip of condensed moisture from cold water pipes.

This dripping occurs all along the pipe, slowly damaging everything beneath—even rotting the floor. It is unsightly, expensive, and unnecessary.

Johns-Manville Anti-Sweat Pipe Insulation eliminates this damaging drip and effects a double economy by keeping the liquid in the pipes cold.

It assures really cold water in drinking water systems; and, where cold water is used in manufacturing processes, it cuts the cost of cooling. It is always cheaper to keep water cool than to re-cool it.

Johns-Manville Anti-Sweat Insulation is a combination of insulating and waterproofing felts built up with a broken joint construction that positively prevents air circulation against the pipe. It is highly effective and unusually economical.

Send for a copy of the Anti-Sweat leaflet.

Every boiler needs a mechanical soot blower and you will save money by buying the best. Ask for your copy of Bulletin 287 describing the new blower.

Floating Features of DIAMOND VALV-IN-HEAD SOOT BLOWERS

One of the most important factors in the success of the Diamond Valv-in-Head soot blower is the floating mechanism which provides a means of taking care of any shifting of position of the blower element without causing dislocation of the wall box, cracking of brick work, or expansion strains on soot blower head and piping.

The Diamond floating mechanism reduces possible binding to a minimum, as it allows the soot blower to move parallel with the wall sufficiently to overcome any change in relative position of wall and bank of tubes.

The floating mechanism is also a direct means of support for the blower element, any movement being taken up by the spring "A" inside of the cylinder. The floating plate "C" serves as a seal to exclude air from the setting.

Elimination of binding of units is only one of eleven important advantages of Diamond Valv-in-Head soot blowers. Others include 50 per cent. saving in steam, 50 per cent. saving in labor, 60 per cent. saving in pipe and fittings, greater efficiency, etc.

Diamond Specialty Ltd., Windsor, Ont.

VALV-IN-HEAD SOOT BLOWERS

Which Stoker?

-You Make this Decision Once-It Must be Right

The Canadian Stoker

JONES Stokers are made in Canada by Canadians and are paid for in Canadian money at par. The exclusive arrangement the extensive engineering resources of the Under-Feed Stoker Co., of America are made available for Canadian power users. This fine strictly Canadian stoker is backed by world-wide experience and unequalled engineering ability.

EXPERIMENT with any equipment is costly--but experiment with mechanical stokers is out of the question. The investment is large; it is made once in a lifetime; snap judgment won't do;--*Which stoker?*

Canadian plants want greater boiler capacity--continuous power day and night when necessary--they want this accompanied by greater economy in burning Canadian coals and by lower labor and maintenance costs.

This means *high-duty stoker firing*, best exemplified by the Jones "A-C" (Automatic-Cleaning) Stoker.

Regardless of the size of the plant, the grade of coal burned or the local conditions to be met, the logical, safe answer to *"which stoker?"* is Jones "A-C."

The new "A-C" catalog goes into detail. Jones engineers with unmatched experience in this specialized field, will gladly make a survey of your plant and give you the full benefit of the best they have learned in installing stokers in many prominent power houses. Investigation implies no obligation.

Possesses Exclusive Features

THE exclusive "Inverted Submerged Bucket" feature of the Armstrong Steam Trap makes it the best trap to handle your condensation.

The Armstrong Trap is small in size and light in weight compared with the ordinary trap. It is easily connected and may be suspended on a pipe line; neither foundations nor pits are required. This and the fact that an Armstrong is self-cleaning and operates with little attention, is the reason for its widespread popularity with big power plants.

RE: PERFORMANCE OF 6" REES RoTURBo PUMP

Dear Sirs:

I have your letter of the 4th, requesting information as to the performance of the new 6-inch REES RoTURBo Pump which you supplied for our Pumping Station, as compared with the old turbine pump which we have discarded.

The capacity and increased efficiency are as follows:

Capacity of Rees Pump per 1 KW. of power per hour: 533 gallons at 120 pounds pressure.

Capacity of old pump per 1 KW. of power per hour: 347 gallons at 120 pounds pressure.

Saving per KW per hour ..... 186 gallons
Saving per KW per day ..... 4464 gallons.
Saving per KW per year (300 days) .....1,339,200 gallons.

The above figures were obtained from readings of the Venturi Meter and the Graphic Recording Watt Meter.

I trust that this information may be of some interest to you, and beg to remain,

Yours very truly,
R. H. Martindale, Supt.

Refrigeration For the Power Plant Engineer

In This the Third Article, the General Principles of the Ammonia Compression System Are Taken Up—The Properties Which Make Ammonia a Good Refrigerating Medium Are Explained

By T. H. FENNER

THE AIR machine, which was described in its general features in the last article, is not in very wide use. The great objection to it is the large space occupied, but it is the advantage of employing a refrigerating medium that is available at all times and all places. This made it very suitable for marine work where vessels might be a long time absent from the home port, or from a place where they could get a supply of any other refrigerating medium. These other refrigerating mediums have not yet been mentioned, but we will now devote a little time to the consideration of what qualities are necessary in a liquid or gas in order to make it suitable for use in a refrigerating machine.

We have seen that in order to lower the temperature of a room by means of mechanical refrigeration that we have to do a certain amount of work. This is in accord with the law of physics which states that it is impossible for any cold body to transfer heat to a hotter body without external aid. In the air machine we have taken a certain amount of air, and by doing work on it, have raised it in temperature and pressure. The temperature is absorbed by the walls of the cylinder in which compression takes place and is carried away by the circulating water. We have thus rejected heat at a high temperature. The air is now allowed to expand and do work on a second piston, the work being obtained at the expense of the intrinsic energy of the air, and this is the temperature. As the temperature was about that of the atmosphere when expansion commenced, the temperature at the end of expansion will be very much lower than the atmosphere and the air is capable of taking up heat from the surrounding air if passed through pipes or even if blown direct into the room to be cooled.

Now the reason that air is a suitable refrigerating medium is because it closely resembles a perfect gas. That is its intrinsic energy, or its capability of doing work is entirely dependent on its temperature. Air has a specific heat of approximately .24, and therefore every 778 foot-pounds of work which is done on it, as in compression, will produce an increase of temperature of 4 degrees.

If this increase of temperature is carried off by the circulating water as fast as it appears, the energy in the gas after compression will be that due to its temperature, and this will be determined by the circulating water. These temperatures are measured from absolute zero. It follows then that when the air is expanded and does work against a piston that for every 778 foot pounds of work performed there will be a drop of 4 degrees.

A refrigerating medium to be usefully employed must have the property of absorbing large quantities of heat per unit mass or volume of the medium. It must also be able to absorb this heat at a low temperature level. It must also be capable of rejecting heat at a moderate temperature level.

There are a number of mediums which fulfill these requirements to a greater or less extent, but the two chiefly used for industrial purposes are anhydrous ammonia and carbonic acid gas. Other mediums are ethyl chloride, sulphur di-oxide, and a combination of the two latter. However for the purposes of these articles we may consider the two first mentioned as the most important.

Anhydrous Ammonia

We have seen that water, in order to be changed from its state of a liquid to that of gas, absorbs a considerable amount of heat, which is known as latent heat. At atmospheric pressure the boiling point is 212 degrees F. while the latent heat is 966 B. t. u. At pressure below the atmosphere the boiling point decreases, while the latent heat increases, the boiling point of water at an absolute pressure of one pound being 101 deg. while the latent heat is 1,034 B. t. u. Obviously, the temperature required to change water to steam even at almost a perfect vacuum is too high to enable it to be of any use as a cooling medium. It requires large quantities of heat to be absorbed, but at a high temperature level. Therefore a successful refrigerating agent must have a low boiling point, and having a low boiling point means that the change of state takes place at a low temperature level, under atmospheric pressure. It also means that the rejection of the latent heat at the same temperature level will reduce the vapor to a liquid again. Following this a little further, it also shows that a medium with a low boiling point at atmospheric pressure will have a still lower boiling point as the pressure decreases below the atmosphere. In order that this property of a low boiling point may be fully taken advantage of, the medium must possess in conjunction with it, a high latent heat. This is so that large quantities of heat may be absorbed at low temperatures approximating that of the atmosphere, and pressures within the limits of the materials which machines are made from. Anhydrous ammonia fills all these qualifications in great measure. It possesses a low boiling point, high latent heat, and can be liquefied at pressure well within the limits of ordinary practice.

Thus at atmospheric pressure anhydrous ammonia boils at a temperature of minus 28.5 degrees F. or 28.5 degrees below zero. Its latent heat at this temperature and pressure is 592 B. t. u.

At pressure of 141 lbs. absolute, or 126.3 by gauge, its boiling point is 75 degrees F. or reversing the process it will liquefy at 75 degrees F. and its latent heat at this temperature and pressure is 508 B. t. u. Therefore if ammonia absorbs heat at a pressure of 14.7 absolute, and it is raised to a pressure of 141.7 absolute, nearly all the heat due to this pressure can be rejected to the circulating water.

Carbon Dioxide CO_2

Carbon di-oxide gas, or CO_2 requries much higher pressure to enable it to perform the functions of absorbing and rejecting heat. Its pressure at zero Fah. is 308 lbs. per square inch, and its la-

tent heat 117 B. t. u. Its pressure at 70 deg. Fah. is 847 lbs. per square inch and its latent heat 63.33. The machines for handling this gas must therefore be of much greater strength, and the quantity of refrigerating fluid for a given cooling effect will be much greater. CO_2 machines were much used in marine work for the reason that the gas is inert, and heavier than air. If any escape due to a break or a bad leak, occurs, the gas falls to the lowest possible position, and there is far less danger of asphyxiation than with ammonia. The latter, being light and volatile, spreads all over, and is very dangerous to those in its vicinity.

In stationary practice, the greater majority of the machines are on the ammonia system.

The Ammonia Compression System

The principle of refrigerating having been shown to be a method of absorbing heat from the system to be cooled, and afterwards rejecting it at a higher temperature, we can examine the actual process in more detail.

If ammonia were plentiful and cheap as water for instance, we could utilize its low boiling point and high latent heat to refrigerate the rooms by simply circulating the ammonia through coils, and letting it run to waste after it had been vaporised. The temperature of the room could thus be lowered by the extraction of the necessary heat required to boil the liquid ammonia, that is 591 B.t. u. per lb. of ammonia. All the heat would not be available for cooling effect, for if the cylinders containing ammonia were situated outside the room to be cooled, they would be at atmospheric temperature, and before the liquid would start to vaporise, its temperature would have to be reduced to the temperature of the room. For instance if the ammonia was at a temperature of 70 degrees, and the cylinder were attached to the valve leading to the coils in the room to be cooled, which we will assume is at a temperature of 60 deg., then each pound of ammonia would give up 10 B. t. u. to the room before the vaporising effect commenced. Its actual cooling effect would then be 581 instead of 591 B. t. u. per lb. of ammonia. As the temperature of the room became reduced, the ammonia would give up more heat to the room and its cooling effect would be lessened.

If we had a room containing 1,000 lbs. of air at 60 degrees, the total heat units in the air would be 1,000 x 60 x .24, the latter figure being the specific heat of air. There would thus be 14,400 B. t. u. in the room. If ammonia at a temperature of 70 degrees was introduced into coils from a cylinder through an expansion valve, its pressure would drop to atmospheric pressure and it would be in a superheated state. It would give up heat to the air of the room until the temperatures were equalized, after which it would vaporize, and each pound would extract from its atmosphere 581 B. t. u. that is the difference between its latent heat and the amount of heat it had given up in dropping to the temperature of the surrounding atmosphere.

If the ammonia gas were going to be discharged into the atmosphere its pressure would have to be at least slightly above that of the atmosphere. Then the lowest temperature to which it could fall would be 28.5 below zero. If the room were to be reduced from 60 degrees to 32 degrees, then the air would have to give up 1000 x (60-32) x .24=4320 B. t. u. The average cooling effect of the ammonia would be 591-10 plus 591-38 divided by 2, or 562 B. t. u. per lb. Then it would require 7.6 lbs. of ammonia to obtain the effect required.

Ammonia, however, costs a considerable amount of money, and cannot be lightly discharged to the atmosphere, outside altogether of the effects on the neighbours. It is therefore necessary to have a machine which can continually recover the ammonia after it has done its work, and convert it again from a gas to a liquid, so that it is once more available to absorb latent heat.

This is where the compressor fulfills its function.

Suppose that instead of allowing the ammonia to be discharged to the atmosphere and lost, we attach the discharge end of the coils to a pump, which will draw the gas from the coils after it has done its work, and on the discharge stroke, discharge the gas into a chamber where it an be stored. If there is no outlet to this storage side, the addition of the gas to its contents will raise the pressure, so that there will be a distinct difference between the suction and discharge side. This means that the gas will have to be compressed from the volume it occupied at the suction pressure to the volume of the discharge pressure.

The work done by the pump in compressing the gas to the smaller volume will appear as heat in the gas, and as additions of temperature cause addition of pressure or volume as the case may be, this will still further increase the pressure. However, some of the heat of compression will be absorbed by the metal of the cylinder in which it is compressed, and if no provision is made to carry it away, these walls would speedily become too hot for working. It becomes necessary then to provide a means of of getting rid of this heat, and the method adopted is in some cases to provide the cylinder of the compressor with a jacket, and circulate cooling water through this jacket. Another method is to inject a small quantity of liquid ammonia into the cylinder with the gas to be compressed, and the heat of compression is utilised to evaporate this liquid. The increased temperature is thus carried away, leaving the gas in the discharge side of the compressor at the temperature corresponding to its pressure, or perhaps slightly superheated.

As the cooling water or other means cannot reduce the temperature of the gas leaving the discharge side of the pump much below 90 degrees, we find that the pressure due to this temperature is about 180 lb. absolute. It follows then that if the pump were to continue working and no outlet provided from the high pressure side the pressure would speedily become abnormal. However, this is not what is done.

The gas from the pump is discharged into a condenser, which takes various forms which will be discussed later. Here the gas is circulated through coils or around coils, in contact with water on the other side. This water carries away the latent heat, causing the ammonia gas to condense, and again become liquid.

This is quite analogous to the action of the condenser in steam practice. We have then a continuous discharge of gas from the pump, and a continuous liquefaction of the gas in the condenser. This liquid falls to the bottom of the condenser, or into another vessel known as the receiver. The outlet from this is by means of a valve which can be regulated to give as small or as large an opening as is required, and is known as the regulating valve, or expansion valve.

We have thus found two distinct sides to the system. A low pressure side, where the liquid is evaporated and takes up the heat required to effect its evaporation from the bodies surrounding it. This side of the system is at low temperature as well as low pressure, and is on the suction side of the compressor or pump. On the discharge side of the pump we have a region of high pressure, wherein the gas gives up the heat which it has absorbed in the low pressure side, and also the heat due to the work performed in compressing it, the result being that it is again liquefied.

Separating these two sides is a valve known as the regulating valve, through which the liquid is allowed to pass from

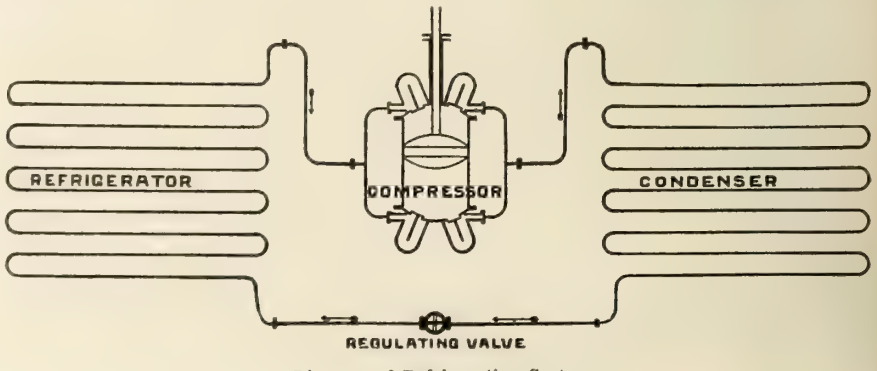

Diagram of Refrigerating System.

the high pressure side to the low pressure side, at a rate determined by the temperature to be maintained. When the liquid passes this regulating valve, its pressure is at once lowered to the pressure of the suction side. Its temperature is still that of the high pressure side, and it first gives up the difference in temperature between the liquid and the contents of the low pressure side. It is then a liquid at low pressure and temperature, and provided the heat is available to perform the function, it will vaporise. This heat is present in the air of the room to be cooled or the brine coils as the case may be, and the liquid absorbs this heat, flashing into a vapor as it does so. It is drawn away by the compressor, and is again put through the cycle of compression and liquefaction, and so on.

It is therefore obvious that if there were no leaks on the system the same charge of ammonia could be used indefinitely. This is pretty nearly so in practice, but due to the leakage at glands, etc. it is necessary from time to time to make additions to the quantity of ammonia in the system to make up for unavoidable losses.

Cooling Effects

From the foregoing we can see that for a definite amount of ammonia circulated at a certain pressure and temperature on each side of the regulating valve, a definite cooling effect is available.

Supposing we have a refrigerating machine, in which the ammonia is coming from the cold room at a pressure of 294.4 lbs. absolute, and is going to the condenser at a pressure of 139.7 lbs. absolute. The temperature corresponding to the suction pressure is approximately zero, and we can assume that the temperature of the brine of the room to be cooled is 10 degrees above that or 10 degrees F. The temperature corresponding to the pressure on the discharge side is 75 degrees, and the latent heat of ammonia at the suction pressure is 572.2 B. t. u. In passing the regulating valve the ammonia liquid will give up to contents of the suction side 75-10 or 65 B. t. u. per lb. This leaves available 507 B. t.u. per lb. for cooling effect. If we are developing 10 tons of refrigeration per 24 hours on the machine, this means that we have 2,800,000 B. t. u. per 24 hours or 120,000 B. t. u. per hour to absorb. Each pound of ammonia is capable of absorbing 507 B. t. u. so that we must circulate 2,366 lbs. ammonia per hour. The volume of ammonia gas at a pressure of 29.4 absolute is 9.19 cubic feet per lb. so that the compressor must be capable of dealing with 2,171 cubic feet per hour, or approximately 36 cubic feet per minute. If the compressor is double acting the cylinder must have a capacity at 120 strokes per minute, of .3 cubic, which gives a diameter of about 7½ inches with a twelve inch stroke.

This of course is only an approximation, but it shows the relation between the amount of ammonia circulated and the refrigerating effect.

It will be noted also that the closer the pressure of the condenser that the dicharge side is to that of the suction side, the less work will have to be done by the machine.

The expression for the efficiency of a steam engine is

$$\frac{\text{Heat Put In—Heat Rejected}}{\text{Heat Put In}} = \text{Efficiency}$$

If we take a steam engine working at 100 lbs. initial pressure, and exhausting at atmosphere pressure, the efficiency will be found from the absolute temperatures at initial and exhaust pressures. This is of course the theoretical efficiency. We have then

$$\frac{T—T1}{T} = E$$

and T is 337 plus 460 while T1 is 212 plus 460. Then we have

$$\frac{152}{797} = .19 \text{ or } 19 \text{ per cent. efficiency.}$$

It is obvious that the greater the difference between the initial and final temperatures, the greater will be the efficiency of the engine.

As the refrigerating machine is a heat engine reversed, it is also obvious that the closer the temperatures and therefore the pressure of the suction and discharge side approach each other, the more efficient will be the machine. Of course there are practical limits to this, but they are well defined. Efficiency is of course the proportion of the amount of work necessary to drive the machine to the cooling effect obtained.

Details of the System

The foregoing is the general description of the ammonia compression machine, and may be taken as that of the CO_2 machine. The details of the machine differ with different builders, but the various parts are of the same general design.

There are two general systems employed in refrigerating, whether the machine use is of the absorption or compression type. We have not yet dealt with the absorption type of machine, but will do so later.

The two general systems are known as the direct expansion or the brine system. In the direct expansion system the ammonia liquid is expanded through the regulating valve into coils which are placed directly in the room to be cooled and the refrigerating is effected directly by these coils. In the brine system the ammonia coils are placed in a tank, in which is a solution of water and calcium chloride, which has a sufficient density to prevent its freezing at all ordinary temperatures. The ammonia extracts the heat from the brine which is circulated through the rooms to be cooled and takes up the heat from there. This heat is again given up to the ammonia the brine being cooled off and returning to the room to absorb more heat. There is thus a refrigerating medium, the ammonia, and a cooling medium, the brine, instead of only just the refrigerating medium as in the direct expansion system.

These two systems have different advantages, according to circumstances, and are both largely used.

In the next article we will describe some of the details of the compression system, before taking up the absorption method of refrigerating.

POWER EXHIBITION

Announcement has been made of the National Exposition of Power and Mechanical Engineering to be held at the Grand Central Palace, New York, from December 7 to 13, inclusive, (except Sunday intervening) by the managers of the Exposition.

The Exposition was decided upon by a group of engineers and manufacturers who had felt the need for such a means of having men get together, exchange ideas, see the latest development in equipment and lay problems before the manufacturer.

The business opportunity where a manufacturer may meet a large assemblage of power plant and mechanical engineers and capitalists interested in power, is significant to firms keen for such business. A number of progressive manufacturers have already engaged space for their exhibits.

The Exposition will immediately follow the annual meeting of the American Society of Mechanical Engineers and it is expected that the exhibits will supplement the programs and discussions at the professional meetings of the Society. The Professional Divisions of the Society will hold sessions relating to fuels, stokers, steam power plants, railroads, steam utilization in the paper industry, textile and gas power, and it is expected that the exhibits at the Exposition will throw interesting light on the papers presented at these sessions of the A. S. M. E. meeting.

That the Exposition will be comprehensive may be inferred from the plans which are to include exhibits of every type of machine, apparatus, equipment, instrument, device and the various materials and supplies necessary in the operation of the complete power plant. The committee decided that its keynote should be " an Exposition of apparatus employed in the generation, distribution and utilization of power."

The Advisory Committee for the Exposition under the chairmanship of I. E. Moultrop of the Edison Electric Illuminating Company of Boston, is comprised of : Milan R. Bump, President National Electric Light Association; N. A. Carle, V. P. and Gen. Mgr. Public Service Production Company; A. G. Christie, Prof. Mechanical Engineering, Johns-Hopkins University; Fred Felderman, National V. Prest., National Association of Stationary Engineers; E. B. Katte, Chief Engineer, Motive Power, N. Y. C. R. R.; Dexter S. Kimball, Prest., The American Society of Mechanical Engineers; Fred R. Low, Editor "Power;" David Moffat Myers,

Some Notes on Gas and Oil Turbines

While There Have Been Many Experimental Internal Combustion Turbines, There Are None in Commercial Use. Some of the Reasons Are Shown by the Author of This Paper

By MAX SCHUELE

Read Before The German Union of Electro Technicians.

THE problem of the gas and oil turbine has busied a great number of engineers during the past twenty years. In spite of these researchers and their many inventions, we fail to find a gas turbine in commercial service. In Germany, the Holzwarth turbine, built by Thyssen & Co., is undergoing a series of severe tests. In other countries nothing has been done save the French experiments with the Armengand-Lemale turbine, which work has been discontinued.

The Holzwarth gas turbine is supposed to follow the fundamental working principles of the Otto gas engine, in which heat is added at constant volume and after performing work the remainder is rejected at constant volume. In fact, the cycles are not identical, since precooling of the gases of combustion has been found to be necessary in the turbine. This precooling is absent in the reciprocating gas engine, although there is an unavoidable cooling during combustion by the jacket cooling water.

Engineers will recognize the thermal disadvantage that lies in this precooling, for if the heat or part of the heat of combustion is allowed to escape, instead of a working process we have merely a heating and cooling cycle. The precooling of the burning gases, in the gas turbine, which are at temperature of 2,800 to 3,500 deg. F., is in sharp opposition to the principles which have, in the gas engine, proved to be fundamentally sound and may be looked upon as the main reason for the failure of so many experimental turbines.

In the constant-pressure gas turbine combustion is carried out continuously and the gases pass out of the nozzle onto the blades at a uniformly high pressure.

The blade surfaces of this type of turbine attain the temperature of the uninterrupted stream of hot gas flowing through the machine. This temperature cannot be held higher than 800 to 900 deg. F. if burning of the blades is to be avoided. As it is impossible to reduce the temperature from that of combustion, say 3,200 deg. F. to 900 deg. adiabatically at the available pressure drop in the nozzles of 150 to 300 lb., the gases must be cooled before entering the turbine. This result is a thermal loss, and an economic loss as well, by reason of the reduced output per machine. The cooling is required not alone to protect the combustion space, where a gas temperature of 3,500 deg. F. is constant. This has been the stumbling block in gas turbine progress up to the present time.

To avoid this precooling loss, the gas and air mixture in the Holzwarth turbine is distributed to from six to ten combustion chambers. The first rise in pressure after combustion starts, closes the inlet valve and opens the burner valve. The gases pass through this valve into the turbine, the potential energy being transformed to kinetic energy at the nozzle, the entire events taking less than one-tenth of a second. This process is repeated by each chamber in rapid succession. Each combustion chamber has a charging as well as a firing period, and as in the gas engine, the cooling jacket combustion chamber absorbs less than 10 per cent. of the developed heat.

It is possible to operate the wheels with a gas temperature of 1,800 deg. F. if the contact lasts only a short time and is allowed by contact with cold air. As for blading, soft electro-iron is used, and this metal appears to stand up satisfactorily, the blades being threaded and screwed into the wheel rim.

The action of the gases in the Holzwarth gas turbine is by no means similar to the action of steam in a steam turbine. The steam issues in a steady stream, while the gas issues from the nozzles of the gas turbine as a succession of impacts, sounding much like machine-gun fire. The bucket wear in the gas turbine is correspondingly increased.

In the Holzwarth machine wheels with pressure stages are not used. The steam turbine has a pressure drop from, say, 13 atmos. to a final pressure of 0.05 atmos., or a ratio of 260, and it would seem that, since the gas turbine has a step-down ratio of from 10 to 20 by 1, a wheel with a single-pressure stage should be ample to give this pressure ratio. One need only consider whether a wheel with several rows of velocity buckets or with but one row is to be used.

Everything said so far for the gas turbine applies to the oil turbine, as the machine is but slightly modified and a fuel valve added.

During the end of December, 1920, an oil turbine, was built by Thyssen, according to plans of Mr. Holzwarth, and put into actual running. The six combustion chambers, each having a volume of 5.18 cu. ft., are arranged around the shaft. The oil centrally injected into oblong combustion chambers by an air-pressure atomizer after the chambers have been filled with fresh compressed air. The oil cloud thus produced fills the chamber completely and is ignited by several high tension spark plugs not shown. The first experiments showed that in this manner heavy oil may be burned without residue and the combustion and resulting pressure are the same as when gas fuel is used. The temperature must be kept high enough to insure ignition, and oil cloud must not come into contact with any cold walls. It is not impossible that benzol-carbon hydrates may be burned without residue. During the experiments it was found that a simultaneous performance of the six chambers could be kept up with a normal rotation of the shaft of 2,700 per minute. Regular running and performance experiments are to follow. Up to now the following facts have been brought out: A medium temperature in the combustion chambers of from 875 to 1,000 deg. is secured, while in the wheel chamber, and at exhaust the temperature is from 800 to 875 deg. In a cast-steel combustion chamber 9 per cent. combustion heat was taken up by the cooling water, while the duration exhaust was found to be less than 0.1 second.

Even if good performance of the experimental gas turbine has been proved, there still remains the difficulty of conveying the greatest possible part of this performance of the shaft. Future experiments will be in the direction of obtaining effective results and improving the form of valves, buckets, the form of the wheel chamber, the time of contact and the air-cleaning system. According to the latest stage of the experiments undertaken in 1921 and the extension of the same, there is a well-founded opinion that the Holzwarth turbine will reach the same grade of development as has the steam turbine. In addition the net thermal efficiency should reach a minimum of 30 per cent. in contrast with the 20 to 22 per cent. obtained by the modern steam turbine.

An examination of the work done in Germany on the gas turbine leads one to feel that there is no basic reason why this form of prime mover should not be made commercially successful. The difficulties yet to be overcome are not greater than those that confronted the early steam-turbine designers. Since the cost of the steam turbine is but a fraction of the total cost of the steam-plant equipment, the gas turbine, when developed into a commercial proposition, should more than compete with other forms of engines. While a low-pressure steam turbine is a necessary appendage, if the greatest efficiency is to be obtained from the gas turbine, it is feasible to far exceed the efficiency of the present-day steam plant even though the gas-turbine exhaust heat be thrown away.

C. A. S. E. Competition Questions

PAPER NO. 6.

Question:—What is a steam trap? Describe at least three well known makes and their operation.

Answer:—A steam trap is a device for automatically removing condensation from a steam line or any other place where it is objectionable without permitting the escape of steam.

Well known makes are (a) the Anderson, containing about the same number of parts as a watch. This is a continuous flow trap with a float operated valve.

(b) The Wright, also a continuous flow trap with float operated valves.

(c) The Strong, a bucket trap, with intermittent discharge.

Question:—Engineers usually have a preference for a certain type of trap. Give three reasons why different types are preferred. The soundness of the reasoning is what will count.

Answer:—Some engineers prefer a continuous flow trap for the reason that as the flow is continuous there can be no shock or water hammer in the discharge line. If the trap is equipped with a water gauge and the float is properly adjusted it can be easily seen whether the trap is operating and it may possibly be known whether it is discharging steam.

Others prefer a bucket trap with intermittent discharge because they claim that as the operation of the trap is audible it can be known by listening whether the trap is operating, also because the valve is either open wide or shut tight, wire drawing is eliminated and thereby cutting of the valve is reduced and the maintenance expense reduced.

Still others prefer a thermostatic trap which permits adjustment so that the temperature of the condensate discharged may be reduced to or below 212 deg. thus getting more work from the heat in the steam. The two first mentioned types discharge water no matter what its temperature may be and the temperature will depend on the pressure.

The two first mentioned types to which may be added the tilting type of trap are the only ones that should be used to protect engines while the thermostatic may be used to drain water heaters, radiators and similar service.

Question:—Describe the operation of a soot blower for return tubular and water tube boilers. Give reasons for their installation proving same by possible savings in dollars and cents.

Answer:—A soot blower is a mechanical device for directing jets of steam so as to remove soot from the heating surface of a boiler. In the case of a return tubular boiler it consists of a movable member located in the combination chamber or in the smoke box connected with an externally located valve by means of which the steam may be admitted. A wheel is provided by means of which the movable member may be rotated.

In the case of a boiler of the B and W type the movable members are placed in the different passes above the tubes.

Soot is a very high grade heat insulator and is very much favored by the coal man for obvious reasons. One quarter of an inch of soot has been found by experiment to account for 38 per cent. of the fuel and ⅛ in. is considered to equal ½ in. of asbestos.

If the thickness therefore could be maintained at ¼ in. and a boiler uses 6 tons of coal at $10.00 per ton per day for 300 days in the year the value of the coal burned would be 6 x 10 x 300 = $18,000. The value of the coal wasted would be 38-100 x 18,000 = $6,840.

This is quite a few dollars but no cents.

Question:—Describe the operation of a safety valve and cite experiences of failure with reasons for failure.

Answer:—A safety valve, of which there are three types, namely the spring loaded, the weight and lever, and the dead weight, is a device for automatically opening at a predetermined pressure to permit the escape of steam from a boiler.

Failure to operate may be due to a desire on the part of the engineer or fireman to avoid waste of steam in which case the valve may be braced in some way so that it can't operate. Or failure may be due to what is called corrosion but which is more likely a collection of matter about the valve which binds it to its seat. (The seat and disc are supposed to be made of non-corrosive metal.)

Question:—Why is the hydrostatic test preferred by boiler inspectors in preference to any other?

Answer:—Preference is due to the incompressibility of water.

Question:—Give some reasons for a reduction of allowable boiler pressure and the methods of guarding against the faults named.

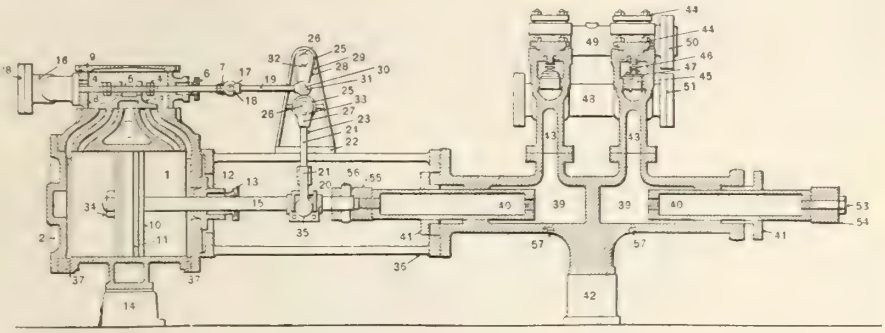
Answer:—Internal pitting and corrosion due to certain qualities in the water. Correction of the water by means of chemicals will prevent this.

External corrosion due to leaks. The remedy for this is the prevention of leaks.

Growing of the shell by faulty caulking.

A hand hole in the rear of the boiler permitting leaking. Hand hole is not allowed now.

A duplex pump consists of two pumps

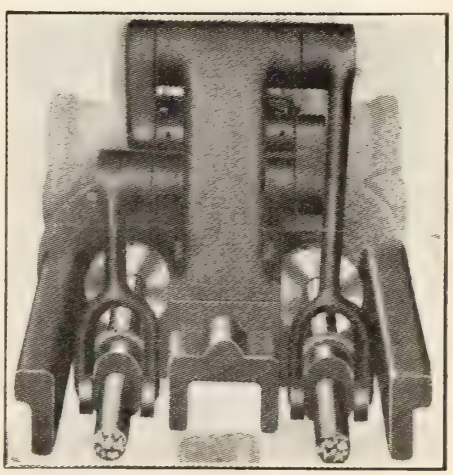


Duplex Pump.

side by side. One side we may call the right hand side and the other the left hand side.

The valve on the right hand side is operated by the left hand pump and the left hand pump valve by the right hand pump. Both valves are direct, the valve moves in the direction the piston is to move or outside edge of valve is the steam edge. One of the rockers however is indirect and the other direct. The valves have no lap either steam or exhaust.

To set the valves the pistons are placed in mid cylinder and the rockers



Valve Driving Mechanism.

set vertical and fixed securely to the piston rods. The length of the valve rods is then adjusted so the valves can be moved an equal distance on each side of the middle of the ports.

Question:— Describe a centrifugal pump and cite some of the reasons given for its adoption. Criticize the reasons given.

Answer:—A centrifugal pump consists of a shaft equipped with radial

vanes revolving in a casing. The water enters at the center of the casing, is caught by the vanes and thrown by centrifugal force to the outside of the casing in which the outlet is located. It occupies very little space which is true. It uses very little oil which is also true. It delivers the water without shock which is true again. No packing of plungers, another truth. Altogether it looks like a good proposition.

Question:—Describe an injector and state fully its action.

Answer:—An injector is a device for feeding water into a boiler by making use of the velocity of steam flowing through an orifice or nozzle to impart velocity to water and thereby enable it to move against a head or resistance.

Question:—Describe a non-return valve and state why in your opinion these should be made standard equipment in all boiler plants?

Answer:—A non-return valve is so designed that it will permit flow in one direction only. It resembles a globe valve in appearance with the spindle detached from the disc, the disc being equipped with a spindle on the lower side working in a guide and on its upper side with a piston working in a cylinder or dash pot to prevent chattering. By means of the screw spindle the valve may be forced to the seat and held there.

The valve is installed in the steam outlet from the boiler in such a way that steam may flow out of the boiler but not into it.

Engineers, firemen and insurance companies are the only ones interested in the adoption of such safety devices for obvious reasons but if engine and boiler room were required by law to be installed directly underneath the head office they might be more interested in their adoption.

Coal Power vs. Water Power For Cities

The Adoption of Hydro Electric Power is Not Always a Distinct Saving, as is Shown Very Clearly in This Article, for Which We Are Indebted to "Steam Power"

By E. E. DILLON

SO MUCH has recently been said and written about the wonderful possibilities and economies of water power that there has been a decided and in most cases an unjustifiable tendency to slight the value of steam power for public utility.

To understand the comparative merits of steam and water power it is necessary to go beneath the surface fact that water power entails no fuel cost and get down to the actual figures and costs affecting communities using steam power and water power respectively.

As distributed at present, water power is in a great many cases costing as much as the same amount of power would cost if produced by coal burned in furnaces properly constructed; and in practically all cases, if the steam plants for which this water power has been substituted had utilized the exhaust steam from engines for heating buildings commercially, the revenue of the steam plant could have been enormously increased and the resulting economy passed on to the public by dispensing with the wasteful operation of a great many private furnaces for heating buildings.

The idea has been disseminated that electricity produced by water power can likewise be commercially used for heating buildings; but that this is true only to a very limited extent is brought out very distinctly by comparing the cost and heat equivalent of electricity with that of coal.

The fundamental unit of power is the horsepower, which is 33,000 foot pounds of work per minute; and its heat equivalent is 42.4 B. t. u.'s per minute or 2,545 B. t. u.'s per hour. Now if a kilowatt hour costs 5.5 cents, which is at the rate of about 4 cents per hp. hour, then 4 cents would be the cost of 2,545 heat units in electrical energy, or about 16 cents for 10,000 heat units, which is the heat value of one pound of bituminous coal that sells in the State of Wisconsin and the middle west for $6.00 per ton in carload lots.

From this it is seen that one pound of this coal will cost three-tenths of one cent, which is the cost of 10,000 heat units of coal energy. But about 75 per cent. is the efficiency obtained when the coal is burned in the best modern power plant furnace, so that 10,000 heat units of energy from the coal actually costs about four-tenths of one cent, as against sixteen cents for 10,000 heat units of electrical energy.

The cost per horsepower for developing a hydro-electric power plant, including transmission lines to market the power, is about the same as for a steam plant, including central heating pipe system, to market the exhaust steam for heating buildings commercially. And the principal advantage of such a steam plant over the water power plant is that it can furnish electric light, power and steam heat for commercial heating of buildings from the same coal; or it can furnish either one of them independently, whereas the water power plant can furnish only the electric power, and at the same time coal must be bought to heat the buildings of the business portion of the city or village, which is in addition to the cost of electrical power.

There is still another very important advantage of the steam plant: When equipped with the best boiler plant equipment, it obtains, as stated before, an average efficiency from coal of 75 per cent.; whereas, the average efficiency of the best house-heating furnace is from 25 to 28 per cent. throughout an entire heating season. Therefore, it is seen that when a power line is extended into a city or village for the purpose of furnishing power and heat, thereby causing the local steam plant to be put ou tof commission, there is a loss to the municipality of the cost of all of the coal that is required to heat the buildings in the business portion of the city or village, for the simple reason that the amount of money paid to the outside power company for electric power will be sufficient to buy all the coal required to furnish all the electric power for the entire city or village and likewise the steam heat required to heat buildings in the business portion of the municipality.

It is evident in either case that coal must be bought to furnish heat for a city or village. So why not adopt the method that will require the least possible amount of it, thereby conserving both money for the municipality and coal for the entire country? Within the past five years there have been no less than twenty cities and villages with populations from 1,200 to 10,000 in the State of Wisconsin alone, that have made contracts of from five to ten years with large water power corporations for power, and have thereby discontinued the use of their steam power plants, which are now lying idle, rapidly depreciating. The average loss to these municipalities, as a result of the contracts thus made, has been over $25,000,00 per year. These statements are facts that can be verified by the records of the utilities in the cities and villages where the contracts were made with the water power companies for power!

POWER EXHIBITION

Payne with offices in Grand Central Palace, New York, to which all requests for fuller information and reservation of space should be made.

Present Day Boiler Room Operation

In This Paper, Presented Before the Metropolitan Section of the American Society of Mechanical Engineers, the Authors Point Out Some of the Features of Boiler Operation

I. E. MOULTROP and R. E. DILLON

THERE is to-day no part of a steam generating power plant where scientific methods can be better employed than in the boiler room. Within recent years extraordinary advances have been made in the design of more efficient apparatus. Various meters and measuring devices have been developed and furthermore analytic methods have come into use for regulation and control.

Modern Advance

We can all point to equipment in operation to-day which bears a very unfavorable comparison with modern built apparatus in the matter of efficiency. I have in mind an electric light plant built in the year 1899. Its capacity was 10,400 kw. in engine driven units. The largest of these engines was 1,600 kw. and this required an oiler and two firemen in attendance. A modern station of the type such as has been erected in various parts of the country within the past three of four years is operated with one oiler and one fireman for each unit of 30,000 kw. or larger. The output per man is, therefore, twenty times as much in the modern station as in the older one.

Furthermore, 2.55 lbs. of coal, or 37,000 B. t. u. are required in the old engine driven plant to manufacture one kilowatt hour. In the modern station this is accomplished with 1.25 lbs. of coal or 18,000 B. t. u. which is almost one-half the former rate.

These figures are representative of the difference between the modern plant and many older plants which are operating to-day. Not all of the increase in efficiency can be attributed to the boiler plant, but a considerable part of it can.

The new larger boilers equipped with modern fuel burning furnaces which are going into so many plants to-day have an efficiency of 80 to 85 per cent. at the operating point of loading, which is a gain in efficiency of 15 to 20 per cent. over types installed ten years ago. The modern furnace and boiler is capable of being forced over peaks to a very much greater extent than the older installations and for this reason where the character of the load curve permits it, a great saving can be made over the practice of carrying banked boilers.

Another factor that is worth noting is the improvement that has been made in increasing the maximum load that can be supplied by a plant with a given number of boilers installed. Contributing to this is the improvement in the efficiency of the Prime Mover and the efficiency of the boiler room apparatus and also the improvement in the method of operating both boiler room and turbine engine. I have some figures in mind of a plant where growth has been normal and where modern extensions have been made which may be indicative of the average large power station. At this plant in 1905 the ratio of maximum load to capacity of boilers was 1 kw. per boiler horse power installed. To-day the rate is 8 kw. per boiler horse power installed.

Efficiency—Extensions

Accepting all these improvements and advances made we can now turn our attention to a discussion of the method of getting the best results from the plant.

If capital has been spent with generous provision for capacity there will be nothing to prevent operating at as low ratings and therefore as high efficiency as is consistent with operating considerations. However, as the load grows it becomes necessary to consider the installation of additional boilers and at this point (provided the present plant can carry the load by forcing) it must be shown that the new installation will permit the plant to be operated more efficiently. To interest capital it must be demonstrated that the improvement in efficiency in the plant due to the additional installation will be sufficient to pay the carrying charges, interest, depreciation and obsolescence, then show a profit or the new construction will not be undertaken. The point where capital charges across the gain due to increased efficiency in the plant determines the extent to which the additional installation can be expected to be carried.

Efficiency—Equipment

Every plant has characteristics which are peculiar to that particular place and these characteristics determine the maximum efficiency which can be obtained and upon which the operating plan must be based. The type of the boilers and fuel burning equipment and other apparatus is pointed out as one factor in the operating plan. If the type of equipment installed permits of a high enough rate of forcing to carry the peaks in the load which are of short duration, banking for these peaks will become necessary.

Efficiency—Load Curve

The character of the daily load curve has an important bearing on operation. Obviously if the load curve is flat and without peaks it will pay to operate the boilers at as near the point of maximum efficiency as is consistent with good operation and labor conditions and as the capacity of the plant will permit. If there are peaks in the load curve, however, the degree of forcing to employ over these peaks and the amount of banking to provide for them will depend on various considerations as will be shown later.

With modern equipment no appreciable gain in labor can be made by operating at higher rating since one fireman can take care of a row of several boilers and the lighting of additional boilers will not decrease the labor appreciably. However, some types of older equipment of small capacity require one fireman for a small number of boilers and the increase of labor with additional boilers is an important item.

The Daily Peak

The question now comes to a consideration of the peak load and whether to force the boilers over the peak or bank additional boilers for it. The duration of the peak enters into this question and the type of the equipment determines how long a given high rate of forcing can be maintained without difficulty in keeping the fires in condition. Considerably higher rates can be employed for short periods than would be practical for longer periods. Furthermore, the extent of high forcing and the period used affects the maintenance costs which mount rapidly with high rates and the time so used.

There is a point at which the loss due to extra fuel burned by forcing at a high rate over a peak is equivalent to the loss due to the alternate case of carrying additional boilers for this peak. I have selected an example to illustrate the importance of finding this point.

Suppose that 150 per cent. rating has been demonstrated to be the most efficient and practical for operation through the day. By forcing all boilers over the peak to a higher than 150 per cent. the plant may be run with less boilers banked while operating on the day and night loads, saving banking losses.

Having determined the number of boilers that should be installed, the number to have lighted and the number to have steaming at any time, the way is prepared to discuss the proper equipment necessary to produce the best results and the method of operation to accomplish this.

Method of Operation

Up to this point we have discussed methods of securing the highest efficiency by using the proper number of boilers and have dealt with a survey of modern equipment. A few words might be of interest now showing what steps the boiler room force takes to meet the changing loads and maintain efficiency.

The boiler room foreman is responsible for having a sufficient number of boilers lighted to take care of the daily peak and the proper number steaming to give best efficiency at all times determined as previously described. He authorises the number of boilers to be brought into

steaming or to be taken out to take care of the load which is indicated on a load sign located in the room.

Here the fireman's duty begins. With the knowledge of the load to be carried and the number of boilers to have steaming to carry this load, he refers to a curve which indicates how much coal he must burn in each furnace to produce the necessary steam. He looks at the tachometers which are scaled in pounds of coal being fed and adjusts the coal feed by means of the rheostat on the stoker's motors until the tachometers indicate the proper amount for output. The tachometers are provided with secondary scales which indicate the approximate air pressure to be maintained in order to supply the right amount of excess to burn coal.

He next adjusts the damper or if induced draft fans are in service, he regulates this to bring the draft over the fire as indicated by draft gauges for this purpose to a slight vacuum, usually about one-tenth inch. Pressure instead of draft would be better over the fire for reasons of efficiency, since it would overcome any tendency toward infiltration, but on account of the danger of blowing out through the doors when they are opened, and also as an aid in maintaining the furnace walls a slight vacuum proves better.

The fireman next looks at the steam flow meter to see if the proper amount of steam is produced and if this proves to be the case he looks at the steam gauge to see if the pressure is maintained.

If the steam flow or pressure indications are unsatisfactory he takes steps to correct this, keeping in mind the adage—"Service first—efficiency second."

After the steam flow and pressure are made satisfactory he turns his attention to the CO_2 recorder or air flow indicator to make sure that the right amount of excess air is being used.

In striving after high efficiency in the boiler room, due consideration must be given to co-ordination with other parts of plant. The efficiency figures in this part of the plant alone should not serve as a criterion for judging the good work of the fireman and the design of the plant. It is the efficiency of the boiler room and turbine room in conjunction which tells the final story, for if 2 or 3 per cent. can be sacrificed in the boiler room in order to gain 4 or 5 per cent. in the turbine room, the result will be justified.

Too often it is thought that the measure of efficiency is the loss to the ash pit and up the stack. This will not prove to be the case until the loss is weighted against the loss of heat to the circulating water in the condenser. Feed water can be heated throughout the great part of the temperature range from either of these two sources of heat. However, by utilizing some of the heat that would likewise go to waste in the circulating water, the turbine room gets the credit rather than the boiler room and provided this credit out-balances the loss in the boiler room, the case is justified.

Rapid Change in Load

The subject of boiler room operation is not complete without a word about the method of handling sudden changes of load with attendant effect upon the efficiency. During the day time, if there is a sudden increase of load, the boilers (if they are handled by the methods which have been discussed) are in a positon to pick it up quickly and can be forced for short periods to high rates without regard to economy. If there are banked boilers, as in winter time, these can be brought in if necessary.

The rapid change in conditions at seven o'clock in the morning on the average lighting company system is a problem which often proves difficult to handle.

If the lighting company is not tied in with other plants only the ordinary increase of the morning load has to be absorbed and the case is simple.

However, if the company is tied in with a water power inter-connection, the problem becomes hard to meet.

In seasons when there is sufficient water, the hydro-electric plants are apt to carry most of the combined load during the night time, and when seven o'clock in the morning arrives, the steam plant is required to pick up that portion of its load which the water plant has been carrying in addition to its own natural increase and cases might arise where this would mean that practically the entire load of the system would have to be absorbed by the boilers at this time.

Taking on the load under these conditions is a very inefficient proposition and an agreement should be reached which would strike a balance between the loss to the hydro-electric due to giving up the load gradually before the system load begins to increase and the loss to the steam plant due to the requirements for absorbing the increased load rapidly.

Emergency Condition

Schedule peaks and peaks that occu regularly are taken care of by forcing steaming boilers or by holding boilers in bank. Frequently, however, an emergency peak is thrown on the system sometimes with warning enough for a few minutes' preparation to meet it and sometimes with no warning whatever.

Thunderstorms

Thunderstorms can usually be discounted 10 or 20 minutes ahead and hot banks prepared, and fire and air pressure built up in the steaming boilers. In cases like this there need be no disturbance in absorbing the load and it can be done with slight decrease in efficiency.

Loss of Load

Another example illustrates a sudden decrease occurring on a lighting system when the tie line to an interconnection system opened bringing out three other lines with it and a total drop-in load of 23,000 kw. resulted. The excess steam discharged through the safety valve. Since it was necessary to reduce the air flow through the fires temporarily, the grates and settings were subject to damaging conditions and the chimneys belched forth black smoke.

In the final consideration of the economy of any plant—that is the ratio of B. t. u. to power produced, due consideration must be given to all factors which affect it, that is, to the apparatus that performs the work and the daily conditions which tend to increase or decrease the economy.

Light Space and Cleanliness

The story of the present-day boiler room operation would not be complete without a word about conditions in the boiler room under which the men have to work. In modern plants it is established practice to spare no expense to make conditions safe and eliminate accident hazards, providing plenty of light everywhere around machinery and plenty of space in keeping the stations clean. The additional expense which has been put into stations to improve conditions has given a high return on investment and this factor alone has contributed in a very great degree toward efficiency.

In conclusion a word may be added to point out that although we have been moving toward greater efficiency in operation we have not reached the end in this direction. Even in the most modern stations only about 17 per cent. of the latent heat stored in the fuel is transformed into electrical energy. The future, therefore, still holds a chance of redeeming in some new station some part of the loss 83 per cent. which at this time can not be overcome.

OTTAWA LODGE C. A. S. E.

Ottawa lodge No. 6 C. A. S. E. held an open meeting in their hall Corner Bank and Frank sts. on Wednesday evening April 36th which was a great success both in attendance and valuable information.

Mr. D. G. Shearer representing the Dominion Flow Meter Co. Ltd., Toronto, gave a very interesting and instructive lecture on The Flow Meter Co. recorder etc. which was illustrated by lantern-slides and the very able and fluent manner with which he handled the subject went to prove him a master.

There were a large number of members, also a goodly number of visitors present.

During the lecture quite a number of questions were asked and very satisfactorily answered by Mr. Shearer and although the meeting ended late the attention and interest given the lecturer went to prove that the subject was much appreciated by all present.

Ottawa Lodge has changed its night of meeting from the 2nd and 4th Wednesday to the 1st and 3rd Monday of each month.

On Monday May 1st will be the election of officers for the ensuing year, also the delegates for convention at Kitchener, it being the last regular meeting of the present year.

The Significance of Chimney Draft

Some Notes on the Pulling Power of Stacks, in Relation to Their Height and Area—The Effect of Wind Pressure and Methods of Staying by Guy Ropes

CHIMNEY or smokestacks are built to serve two purposes. Usually the first consideration is the draft required but some thought must almost always be given the question of delivering the products of combustion at a sufficiently high point so that they will not be obnoxious to the community. This latter consideration is often governed by local ordinances, says the "Locomotive."

Draft, or the ability of a chimney to draw air through the fuel bed, depends upon the fact that the weight of a given volume of air or gas decreases when it is heated. To fully explain the principle of chimney draft, resources must be had to the atmospheric pressure. The air or atmosphere in which we live envelops the earth like a great hollow sphere or shell which physicists have estimated is about sixty miles in thickness. Because of the pull of gravity on this envelope of air a pressure is exerted upon the surface of the earth which amounts to 14.7 pounds per square inch of area at sea level. The further we go from the surface the less the pressure becomes. For instance, suppose we have a boiler room at the sea level with a chimney 100 feet high. The pressure in the boiler room would be 14.70 lbs. and the pressure at the top of the stack would be about 14.65 lbs. The difference of .05 lbs. would be caused by the 100 ft. of air between the two levels. If we consider the furnace of the boiler when there is no fire in it, the pressure on the under side of the grates would be 14.70 lbs. and on the upper side of the grates it would also be 14.70 lbs. Of this 14.70 lbs. pressure, .05 lbs. is caused, both on the upper and lower side, by the 100 ft. of air that we have under consideration. Suppose, however, that we put a fire under the boiler and that the gas in the chimney becomes so heated and expanded that the weight of one cubic foot is but one-half that when cold. The pressure exerted by 100 ft. of this gas in the chimney would only be one-half its former value or it would be .025 lbs. To this we would have to add the weight of the cold air above the top of the chimney (14.65 lbs.) so that the total pressure in the furnace above the grates would be 14.675. But we have not heated the outside air so that the pressure under the grates would remain at 14.70 lbs. There would then be a difference in pressure on the two sides of the grates of .25 lbs. which would cause air to flow through them. As fast as this occurred, however, combustion would take place thereby maintaining the temperature in the stack and the difference in pressure above and below the grates.

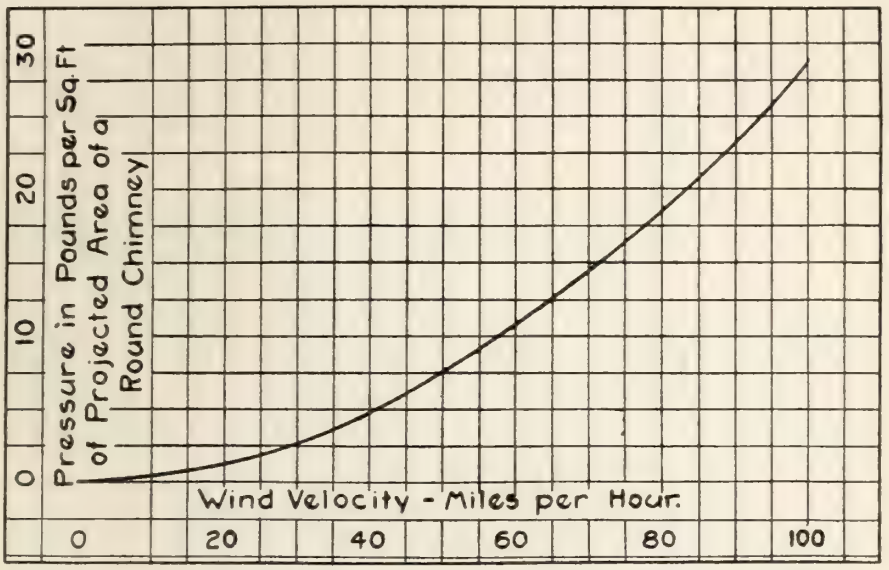

Diagram For Wind Pressure.

Thus we see that there are two fundamental methods of increasing the draft. The one is to increase the difference in temperature between the inside and the outside of the stack. The other is to increase the height of the stack while holding the temperature difference the same. In the interest of economy, however, as much heat as possible must be taken from the hot gases which in turn decreases their temperature and requires a greater height of stack.

The cross-sectional area of a chimney depends upon the kind of coal, the amount to be burned in a given time and the velocity of the gases in the stack. The height depends upon the draft pressure required to burn the coal at the desired rate and also upon the temperature of the gases in the stack. The large number of unknown variables make the field of chimney design a difficult one and proportions that have been found, in years of practical experiment, to give good results are relied upon rather than theoretical formulae. The proportions as given by Kent's Hand book for Mechanical Engineers have been used for many years and are as given in table 1.

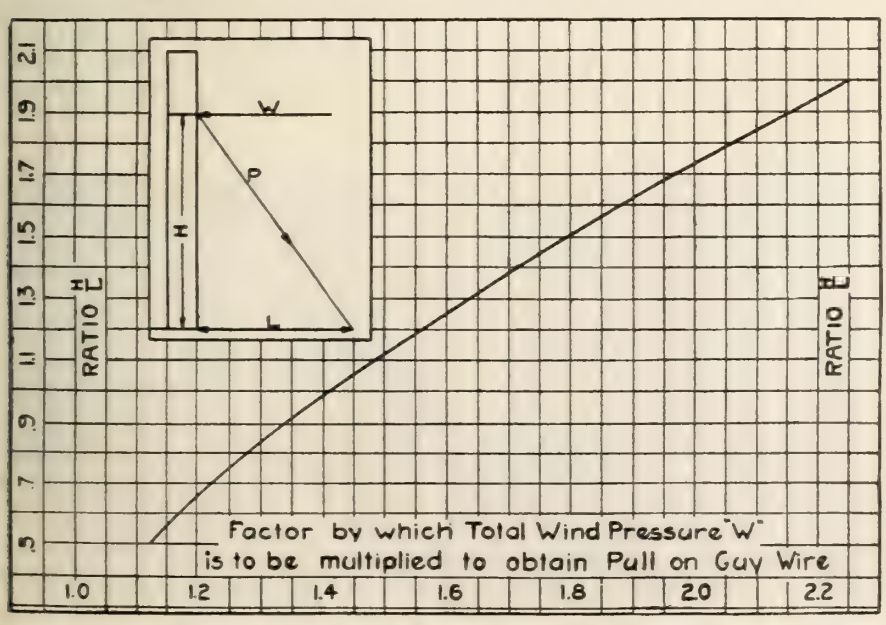

Diagram For Guy Ropes.

Chimneys are built of brick, concrete or steel. The first two materials named are only used for self-supported stacks or those whose weight and design of base are such that no guy wires are necessary. Steel chimneys are also built to be self-supporting but the smaller size steel chimneys are usually braced against the wind pressure by the use of guy wires.

The wind pressure varies greatly with the wind velocity. With a round stack the relation between the two is expressed by the formula $P = .0029\ V^2$ in which P is the pressure in pounds per square foot of projected area of the stack and V is the velocity of the wind in miles per hour. This relation has been plotted as a curve in Fig. 1. From this curve we see that low wind velocities produce but little pressure and that the higher velocities increase very rapidly. A wind velocity approximately 100 miles per hour is classed as "an immense hurricane" and while such a wind storm is unheard of in many sections of the country, nevertheless, engineers base their designs of guy wires on this velocity. It will be noted that a wind velocity of 100 miles per hour corresponds to a pressure of 30 lbs. per square foot of projected area. We might add that by "projected area" is meant the diameter of the stack multiplied by the height. Thus the total pressure on a 100 ft. stack 24 inches in diameter, would be 2 ft. x 100 ft. x 30 lbs. or 6,000 lbs. total.

Guyed stacks are not commonly built in sizes greater than 6 ft. in diameter or 100 ft. in height. They are guyed with one, two or three sets of guys having three or four strands in each set. The greater number of sets of guys the greater, of course, will be the stability of the stack. For general practice it might be well to use one set for stacks 50 feet or less in height, two sets for stacks between 50 and 100 ft. and three sets for stacks above 100 ft. The guys are attached to the stack by means of an iron ring made in sections with lugs and at the lower end are secured to a building or to an anchor, such as a heavy block of concrete, buried in the ground. If but one set of guys is used, the ring in the stack is usually placed at about two-thirds of the height above the base. If two sets are used it is common practice to place one at 2/5 and one at 4/5 of the height.

In determining the size of the guy wires it is assumed first of all that the wind is blowing directly in line with one of the guys. If one guy is used it is assumed to carry the load caused by the wind pressure on all the stack above the guy ring and that on two-thirds of the distance between the ring and the foundation. If two guys are used the upper one is figured for all the stack above its ring plus two-thirds of the space between the upper and lower ring; the lower one is figured for two-thirds of the sections both above and below it.

The guy wires must, of course, make an angle with the stack and the pull on them will be more than the total horizontal force of the wind. The curve in Fig. 3 has been worked out to show the relation between the two. For ready reference the ratio of height to horizontal distance has been plotted instead of the guy wire (See the sketch in Fig. 3). Thus for a ratio of H of 1.4, which represents average practice, the total wind pressure W that any one guy is to carry should be multiplied by 1.5 to obtain the actual pull on that guy. To allow for the initial tension, that must exist even where there is no wind, this assumed load should be increased 50%.

TABLE I.
Size of Chimneys for Steam Boilers.

Diam.	Height of Chimney in feet								
Ins.	50	60	70	80	90	100	110	125	150
	Commercial Horse Power of Boiler								
18	23	25	27	29					
21	35	38	41	44					
24	49	54	58	62	66				
27	65	72	78	83	88				
30	84	92	100	107	113	119			
33		115	125	133	141	149	156		
36		141	152	163	173	182	191	204	
39			183	196	208	219	229	245	268
42			216	231	245	258	271	289	316
48				311	330	348	365	389	426
54					427	449	472	503	551
60					536	565	593	692	662

As an example, suppose that we have an 80 ft. stack, 4 ft. in diameter, to be supported by two sets of guys. The upper set would be placed at 4/5 x 80 or 64 feet from the base and the lower set at 2/5 x 80 or 32 feet from the base. The wind pressure carried by a guy in the upper set would be:—

(16 ft. + (2/3 x 32 ft.) x 4 ft. x 30 lbs. = 3199 lbs.

Assuming a ratio of $\frac{H}{L}$ of 1.4 we must increase this by 50%

3199 lbs x 1.5 = 4798 lbs.

This must be increased again by 50% to allow for initial tension which is the assumed maximum pull that the guy will ever be called upon to withstand. From Table II we find that a 9/16 inch galvanized iron rope would carry the load.

The lower guys would figure as follows:—

((2/3 x 32) (2/3 x 32)) x 4 30 = 2558 lbs. wind pressure, 2558 x 1.5 x 1.5 = 5775 lbs. total,

which would call for a ½ inch galvanized iron wire rope. Note that in the selection of a guy rope practically no factor of safety is assumed other than the remote possibility of the wind pressure reaching a high value and the allowance that is made for initial tension. However, if the wind velocity is 50 miles per hour, which is classed as a "very high storm" the wind pressure is but 7½ lbs. per square feet instead of 30, so that ordinarily, the guy is not heavily stressed. Of course in localities where extreme high wind velocities are common, a larger strand should be used.

The sections of the stack should "shingle" on the inside. This is to avoid, as far as possible, the entrance of water into the joint which might occur when the stack is not in use. To protect the joint on the outside it may be caulked tight. The rivets, for a stack made of ¼ inch plate, would ordinarily be ½ inch in diameter and spaced 2 inches on centers.

Little can be done to prevent corrosion on the inside of a stack but the outside should be protected by a good stack paint and a new coat should be applied from time to time.

TABLE II
ULTIMATE STRENGTH OF GALVANIZED IRON WIRE ROPE COMPOSED OF 6 STRANDS AND A HEMP CENTER, 7 OR 12 WIRES TO THE STRAND

diam. in. Approx.	in. Circum.	Strain in lbs. App. Break.
5/16	1	2800
3/8	1 1/8	3600
7/16	1 1/4	4600
1/2	1 1/2	6400
9/16	1 3/4	8800
5/8	2	11600
3/4	2 1/4	14600
13/16	2 1/2	18000
7/8	2 3/4	22000

UNDERFEED STOKER MOVES

The Underfeed Stoker Co. of Canada announce the removal of their head office from 81 Victoria street to 505 York Building, 146-152 King Street West, Toronto.

(a) Stack wrecked by wind. (b) Gin pole being erected. (c) Gin pole in place. (d.) New stack going up.

Boiler Explosion at Bridgeport

Monday, the second of January, 1922, was a legal holiday in many parts of the country and a large number of manufacturing plants and business houses closed for the day. Celebrations to welcome the New Year were numerous but the forces of nature stole a march on everyone and staged, in a boiler explosion at Bridgeport, Conn., a demonstration that outdid them all. Whether or no there was much temptation placed in the way of those who celebrated the season, certainly much encouragement was given the forces that can be stored in a boiler to show what they could do.

The boiler was an old one—we do not know just how old, but we believe that the age was at least twenty years—of the locomotive type and of lap construc-

Fig. 1.

tion. The metal was severely corroded and, worst of all, repairs had been made by autogenous welding. The owners had bought the boiler, apparently with the best of intentions, from a second hand dealer and probably this dealer sold the boiler with the belief that it was in reasonably good condition. It was said also that an inspector had passed the vessel as being acceptable for a pressure of 100 lbs., and with this belief the owners thought they had secured a bargain. Two months after the boiler was installed, however, the explosion occurred and property damage to the extent of about $8,000 was done.

Newspaper reports stated that the man in charge of the plant at the time had just stoked the furnace of the boiler and had walked a short distance away to turn on an electric light, when the accident occurred. It was said the man was hurled out of the boiler room by the force of the explosion, but miraculously escaped injury.

There were two boilers at the plant and these were placed side by side in a basement over which there was a one-story shed. When the explosion occurred, the barrel-sheet of the boiler was torn off and the remainder—by far the larger part—was hurled up and against the brick wall of an adjoining building, tearing a hole in it and coming to rest in the position shown in the picture above. The barrel-sheet itself was blown up and over the remaining part of the shed and landed in an alley-way between the shed and the next building, as shown in the picture on the opposite page. Just above the third window from the left of the picture the scar may be seen where the plate first struck the brick wall.

A close-up view of the part enclosed by a white circle in Fig. 1 is given in Fig. 2 above and in it may be seen the welding that was done at the junction of the longitudinal and girth seams. The other end of the point is illustrated in Fig. 3 in which the corroded condition of the plate can be fairly well distinguished.

Competent inspection would have shown the danger of using this boiler and the loss in time and money which the owners had to suffer would thereby have been avoided.—Travelers Standard.

After The Explosion.

TORONTO NO. 1 C. A. S. E.

The Toronto Lodge No. 1 of the Canadian Association of Stationary Engineers held their regular meeting at Cumberland Hall on Tuesday May 2nd, the annual election of officers being part of the business of the meeting. The following gentlemen were elected to hold the various offices for the ensuing year:—

President:—Bro. McLaren.
Vice-President:—Bro. Clewes.
Recording Sec.—Bro. Brown.
Financial Sec.—Bro. Golightly.
Treasurer:—Bro. Soucy.
Conductor:—Bro. Quinlan.
Doorkeeper:—Bro. Thomas.
Trustees:—Bros. Stephens, Fowler, and Quinlan.

After the election business was disposed of, the educational committee took hold of the proceedings, and questions put by the members were answered and illustrated on the blackboard.

The Gas Turbine

WHILE THERE is not a great deal heard about it, the search for the commercially possible gas or oil turbine goes on steadily. As is often the case, the patient searchers are for the most part Germans, this being a line of endeavor that seems to suit their methods. A certain amount of success has attended their efforts, but it has all been along experimental lines, and there is not as yet any machine working in any industrial field.

The gas or oil turbine probably marks the ultimate limit of the possibilities of the heat engine, as the reciprocating triple or quadruple expansion engine marked the limit in reciprocating steam engine practice. It is a noteworthy fact, that in the application of steam direct to the piston of an engine, but little advance has been made from the time of Watt, as far as the principle is concerned. The splitting of the expansion of the steam into several cylinders, which only came after many years, was but a modification which did away with some of the troubles of liquefaction in the cylinder, due to extreme ranges of temperature.

With the internal combustion engine, the full utilisation of the heat of combustion is interfered with by the necessity of keeping the temperature of the cylinder walls down to a point which makes it possible to avoid distortion, and consequent excessive friction, or seizing. This is accomplished by means of water jackets, or as in the case of the Still engine, utilising the latent heat of steam to cool the jacket, by evaporating the water, and then using the steam so formed, to do useful work on the opposite side of the piston.

With the internal combustion turbine, the difficulty has not been to cool the walls of the turbine casing, but to prevent the rotor itself from getting to a temperature at which it would be distorted. This again has meant that the heat of combustion must be dissipated to some extent before the gases are allowed to come in contact with the blades of the rotor. This again decreases the thermal efficiency. In a paper read before a German electrical society these points are explained, and the latest attempts at a solution of the problem explained. This article appears in another portion of this issue of "Power House."

The success of the gas turbine would mean that very low grade fuels could be utilised in gas producers, and the gas thus formed employed to drive a gas turbine at a much higher thermal efficiency than is possible even in the best internal combustion reciprocating practice, and away beyond steam turbine practice. There is no doubt but the difficulties so far encountered will be eventually overcome. It is not so long ago that there were many prophets who insisted that the Diesel engine could never be utilised for large seagoing vessels, but to-day there are hundreds of such ships afloat, and making money for their owners where the steam propelled vessel has to be laid up.

It may not be so very long before we are recording the first successful installation of a gas or oil turbine in a central station or industrial plant.

* * * *

Buying Second Hand Boilers

THE DANGER of buying second hand boilers without adequate safeguards is well illustrated by the account of an explosion at Bridgeport in this issue. We do not mean to say by this that second hand boilers should not be purchased at all, but when they are, it should only be after very careful and competent inspection by a totally disinterested party.

In this case the boiler was of uncertain age, was badly corroded, and further had been autogenously welded. Such a combination would never have been passed by an inspector with any experience and judgment, although it was said that this particular boiler had been inspected. If so, it was probably by an inspector procured for the job by the dealer.

There are plenty of dealers in second hand boilers who would not sell a boiler to a client if they had doubts of its safety for the purpose it was to be used for. There are others, unfortunately, who have no such scruples, but will deliberately misrepresent the condition of the boiler in order to make a sale.

The history of a boiler should always be ascertained when buying it, as this will often help in determining its condition and capabilities. Age is a vital factor, and the usage it has been subjected to is another. Neglect of these precautions let the purchasers of the boiler in question in for a very severe loss, and only by good luck was the loss of human life escaped.

A small fee paid to an inspector of recognized standing would have saved many thousand dollars in this case.

Australian Coal

AUSTRALIA is the happy possessor of many fine coal fields, the principal area in New South Wales having a known area of 200 square miles with varying thicknesses up to 27 feet of the very best coal. In Queensland recently a seam, probably the thickest in the world, was proved to have a thickness of at least 93 feet. The coal is remarkably free from ash, says the Communical Intelligence Journal, and the vast seam is pure coal, devoid of any clay bands. The coal varies from 200 feet below the surface to 83 feet only, and at this latter depth, to decrease the cost of mining, it is proposed to use the open-cut system. It is stated that on reasonable borings there are 450,000 million tons of coal proved.

OUR QUESTION BOX

Questions are invited from readers regarding power plant operation and difficulties encountered

COPPER PIPES IN SUPERHEATERS

Question:—Why are not copper pipes more generally used in the construction of superheaters?

Answer:—The objection to copper pipe for superheaters is its liability to loss of ductility by constant service and repeated expansion and contraction. It is of lower tensile strength than steel, and costs more. In the high temperatures used in modern superheaters copper is not nearly so reliable as steel.

(2) If 100 B. H. P. be absorbed by a single stage air-compressor, maintaining an air pressure of 100 lb. per sq. in., what B. H. P. could be recovered from a simple slide-valve engine using all the compressed air as a working medium, the engine being 300 ft. distant from the compressor?

Answer.—The power available from an air motor is generally about 45 to 50 per cent. that of the useful work delivered by the engine or motor driving the compressor. Thus in the case given, the work of compression and overcoming friction in the air compressor is 100 B. H. P. which gives about 85 B. H. P. actually used for compression. The distance the air is to be carried through mains to the engines is relatively short, and if the main is of ample size the drop in pressure will be small. If the air is delivered to the engine at atmospheric temperature, the efficiency of the whole system will be about 50 per cent., or the engine should deliver about 50 H. P. If the air is reheated before delivery to the engine then the efficiency will be correspondingly increased. If air is allowed to expand in the cylinder of the engine from 100 lbs. gauge to atmospheric, and its temperature at the starting point is at that of the atmosphere, considerable trouble will be experienced because of the refrigerating effect.

A MENSURATION PROBLEM

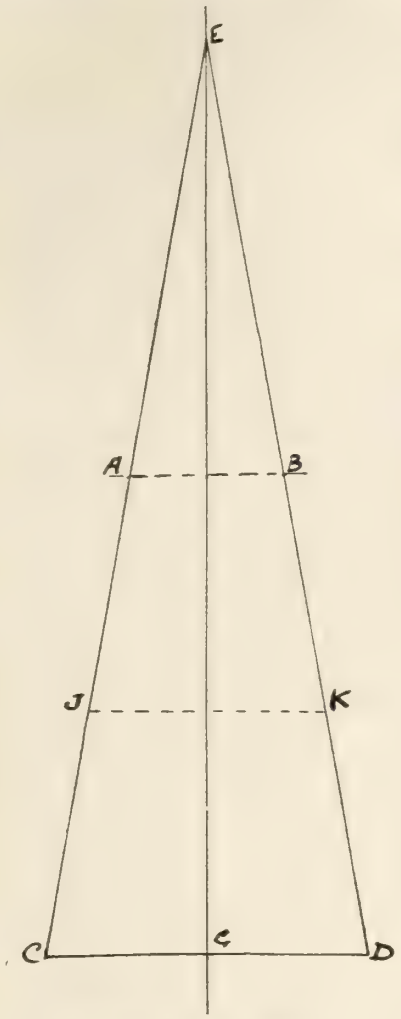
By E. G. W. Montgomery

Re mensuration problem on page 35 of your issue for April 5.

The following solution is suggested as simple and direct.

Complete diagram of plate A C D B to form triangle E C D. Then E F=60″ and E G=120″.

$$\text{Area of plate} = \frac{20 \times 40}{2} \times 60 = 1800 \text{ sq. in.}$$



Extension of plate outline.

$$\text{Area of EAB} = \frac{20}{2} \times 60 = 600 \text{ sq. inches.}$$

$$\text{Area of EJK} = \frac{1800}{2} \times 600 = 1500 \text{ sq. in.}$$

Area of ECD=17800+600=2400 sq. in.

EJK : ECD : :5 : 8.

JK represents line of cut.

$$\frac{EJK}{ECD} = \frac{EH^2}{EG} \quad \therefore EH^2 = \frac{120^2 \times 5}{8}$$

$\therefore$ EH=60×1.581=94.86″.

$\therefore$ HG=120—94.86.

ENGINEERING NEWS

Robt. Gardner & Sons of Montreal, are manufacturing the machinery and equipment that will be installed in the biscuit factory for David & Frere at Maisonneuve, Que. The contract price of machinery will be about $50,000.

* * * *

An entirely new installation of heating and ventilation for the Myrtle Street public school of St. Thomas, Ont., has been recommended by Donald Stewart, consulting engineer, of Windsor and Hamilton.

* * * *

The Robertson Construction Co. of Niagara Falls, Ont, has secured the contract for the erection of a new sub-station for the Hydro Electric Division at Niagara Falls. The cost of the structure will be about $67,200.

* * * *

Reports from Saskatoon, Sask., announce the following contracts closed for construction work. A new chemistry building at the University of Saskatchewan will be commenced shortly, the estimated cost to be about $440,000. Bennett and White of Calgary are the general contractors. Green and Lister of Winnipeg have received the contract for plumbing and heating. Wathton Electric Company of Saskatoon have obtained the contract for the electrical work.

* * * *

Tenders for the masonry, brick and carpentry work on the new civic hospital will be received May 4. The trustees will then call for tenders for heating, plumbing and ventilation of the main building and possibly also for the power house and building for female help, leaving only the nurses' home, plans for which are well under way.

* * * *

The general contract for the construction of the collegiate institute and technical school of Guelph, Ont., has been awarded to the Yates Construction Co. of Hamilton. The contract price, namely $252,500, is to include all work with the exception of plumbing, heating and ventilation. The contracts for the last three mentioned has been awarded to W. C. Edge and Co., of Ottawa, at a cost of practically $54,000. The building will be of reinforced concrete.

The Operators' Point of View

THE ENGINEER

Who works with sweaty brow, and black?
The Engineer.
Who strains his muscles, cricks his back?
The Engineer.
Who cools the bearings, stops the leaks
Makes wheels go round though they be freaks,
And always finds the thing he seeks?
The Engineer.

Who sees the fireman does his work?
The Engineer.
Who sees the boilerman doesn't shirk?
The Engineer.
Who, when the steam is going down,
Will dig right in without a frown
And help the fireman? "Darn the clown!"
The Engineer.

Who needs a temper like a saint?
The Engineer.
Who listens to the engine's plaint?
The Engineer.
Who finds the squeaks, locates the knocks?
Who keeps the whole plant off the rocks?
The Engineer.

Who, when he dies will go to heaven?
The Engineer.
Who'll have his little sins forgiven?
The Engineer.
Whom will Saint Pete a welcome show
And say, "To hell he must not go,
He had his troubles down below,
The Engineer."

R. A. WOODS.

STEAM TRAPS
By James E. Noble

A piece of apparatus used in power plants, be they ever so small, is the steam trap, and very often they receive less attention than any other important attachment in the plant. An expansion trap may be bought and connected by some jobber who neglects to blow out the pipes before making the final connection. Result, pipe scale, pipe joint paint, or dirt, or all three, are blown into the trap. Such a trap usually has a small discharge opening, and a small piece of dirt may close it, and the trap be condemned. If it is a trap containing several valves one or more of the valves may be made inoperative, because of someone's lack of knowledge or care. An improper trap for existing [illegible] used, resulting in its being classed as "no good." A trap of the expansion type should have a fair sized receiver to take care of a sudden rush of water as this type is often slow in discharging when it is a bit warm. In all cases a steam trap inlet pipe should be provided with a strainer and a blow-off valve near the trap. Many manufacturers are alive to the importance of this and supply a combined blowoff and strainer fitting as part of the equipment, the cost being included in the price of the trap. Some provision should be made so that the discharge of the trap can be examined without doing any disconnecting. The trap may have a hidden discharge, it may be blowing steam or it may not be discharging at all. This is one of many points to the credit of the visible tilting trap, as it is impossible not to note whether it is functioning or otherwise. There are many different designs of this type. Some of them can discharge steam steadily when out of order and allow costly leakage if neglected. Very often traps are installed in dark, out of the way corners, and when they get out of condition they stay that way until collected water forces their examination. Usually the trouble can be traced to neglect. Many modern steam traps have proved beyond controversy that they will function properly month after month without one cent of expense for repairs if they are kept clean. I have installed many steam traps and repaired others. In at least 90 per cent. of the repair cases, collected dirt in the trap itself, or in the pipe connections or in the valves was the trouble. Sometimes packing is allowed to harden, or the glands are so over-tightened as to affect the proper operation of the trap. A trap is something like the old reliable duplex pump; its operation is simple and easily understood, given a little care and fair treatment and it will prove a steady worker.

A FEW USEFUL TIPS
By John Thorn

The little bits of knowledge, short cuts to get a certain result, etc., often prove of great value in engineering. Some men make a practice of carefully filing such items for reference, so that they can be located in a few moments when wanted. This means considerable labor, but some particular bit of information is apt to prove just the one thing wanted in an emergency, important enough to pay for all the trouble taken. The items filed for reference should be such as are not generally found in text books or books of standard rules. The following will give an idea of what I mean.

A short rule for finding the change required in the length of belt pulleys when one of the pulleys on which it runs is changed for one of different size, is as follows: Take three times the difference between the diameters of the pulleys and divide by two. The result will be the length of the belt to cut out or put in.

It is generally known that increasing the voltage on an incandescent lamp will make the filament hotter and thus give out more light, but it is not so generally known that the increase in light is greater than the increase in watts, so that the higher the voltage the less the watts per candle power. Of course, adopting this plan would shorten the life of the lamp.

A rule often omitted from text books is one to find the length of a cross belt. To do so, square the diameter of the large pulley and the distance between centres, add together and extract the square root of the sum; subtract from this the distance between centres and multiply the remainder by two and add the distance around outside of both pulleys.

Theoretically a pump will raise water when the surface of the water is 33 feet below the pump plunger and valves. Some writers claim that good results are obtained when the lift is from 27 to 30 feet. My own experience convinces me that a pump will not give satisfactory service, if the lift exceeds 25 feet. It may lift a foot or two more but the flow will be reduced and the necessary power to operate the pump will be increased. A suction air chamber will help some, but from many years' practical experience in pump work I am convinced it will be good business not to exceed a 25 foot lift unless absolutely compelled to do so. As stated, a suction air chamber will be of some help but they have the habit of becoming filled with water just at a time when they should be empty.

Editor's Note:—An air vessel on the suction side of a pump is useful where there are very long lines of pipe between the source of supply and the suction of the pump. In this case the water in the suction pipe attains a large amount of energy due to its velocity, and if no air vessel is fitted, this will

cause violent pulsations and shock.

In the case of a direct lift, an air vessel would be of no service on the suction side of the pump. If there were no friction in the pipe or pump passages, and the pump could effect a perfect vacuum in the suction pipe, then the lift would be governed by the pressure of the atmosphere, and with a barometer pressure of 30 inches mercury, corresponding to 14.7 lbs., the pump would lift water from a depth of 33.8 feet.

In practice from 25 to 26 feet is the maximum depth.

A FEW NOTES

By W. D. Booker

Some years ago we replaced a steam boiler feed pump with a power pump keeping the steam pump for washing boilers, etc. The power pump was a decided success, so when the steam end of our jet condenser needed a lot of repairs we scraped everything but the condenser head to which we attached a power vacuum pump making our condenser power driven. After several years I can safely say the change was a very big improvement.

Later we took down the auxiliary pipe line and tapped pipes into the main steam pipe at the different places where steam was desired. These changes reduced the lost heat so much that the engine room was far from warm during the cold weather, so last fall we installed three heaters. These heaters were connected up with the condenser and carried a vacuum. The steam was drawn from the exhaust pipe between the engine and condenser while the returns were piped into the condenser between the valve decks on one end.

When the condenser plunger moves back on a suction stroke it reduces the pressure, or lowers the vacuum, in the cylinder and between the valve decks, below the vacuum in the condenser head. This difference in pressure causes the suction valves to open and the water to flow in.

By connecting the returns between the valve-decks this lower vacuum was utilized to cause a circulation in our vacuum heating system. A check valve was placed in return pipe close to condenser to prevent water entering on the return stroke of plunger.

Last winter the engine-room was comfortable and the steam for heating it cost nothing.

With a vacuum heating system it takes about three times the heating surface as with a few lbs. back pressure, and the supply pipes should be very large.

STEAM JET CONVEYORS

G. S. Hamilton.

During the past few years the steam jet conveyor as a method of handling ashes is growing more popular among power plant executives.

Wherever it has been introduced, it has been received with satisfaction and favor. It is handling ashes not only successfully, but also quickly and economically.

The steam jet ash conveyor consists primarily of a line of pipe of extremely hard metal laid of 6-8 or 9 inch diameter, laid in a trench in the boiler room floor, or in an ash tunnel, if there are stoker pits. This pipe line leads from the boiler room to a disposal point outside. Intakes for the troduction of ashes are located before each ash pit.

A jet of high velocity steam provides the motive force. This steam jet is introduced into the conveyor system usually at an angle in the line at a point just beyond the last ash intake opening. A specially designed body fitting is provided at this point, so constructed as to not only properly hold the steam nozzle, but also to deflect the flow of ashes around the angle in the line.

The ashes are drawn by suction to the steam jet and thence are propelled by ejection the remainder of the distance along the discharge line.

In operating the conveyor, the steam valve is opened, the plug or cover removed from the intake and the ashes are fed into the system. Clinkers, broken into pieces small enough to enter the conveyor system can be discharged through the conveyor.

Ashes should be dry. It is not necessary to quench them before feeding into the conveyor.

Users of the steam jet ash conveyor like it because of its labor saving abilities. There is no doubt about its merits in this respect. Only in plants having a large accumulation of ashes is an ash handler necessary as usually the fireman handles the ashes as he cleans his fires.

The usual ash handling gang is laid off or put to more productive labor.

Even when its labor saving qualities are not so manifest, the steam jet proves its popularity by its convenience.

Some plants are so located and laid out that even where the fireman may handle the ashes in his leisure moments it becomes a difficult task to do so. Firemen who work under difficult conditions are dissatisfied. They change jobs frequently. The convenience of the conveyors lessens work, adds to efficiency, and produces a better morale.

Cleanliness is a merit of the steam jet conveyor. One well-known manufacturer has so designed equipment that there is positively no flying dust when the ashes are discharged into the usual storage tank. This manufacturing concern backs up their claims by a guarantee written in the contract.

This is a boon to the power plant that is situated in a high class residential district, or is developing power for a works where unusual cleanliness must be observed. Flying ash dust in the past has been an unavoidable nuisance—now the modern plant may avoid it entirely.

Steam jet ash conveyors can be installed in practically 95 per cent. of the power plants developing high pressure steam by coal. An economical installation requires a working pressure of at least 70 pounds. Ashes can be handled at the rate of six—fifteen tons an hour depending on the size of the conveyor system and the general layout effecting plant conditions.

The steam consumption is low, it being necessary to use steam only while the conveyor is in operation. The speed at which the conveyor can be handled reduces the cost of steam per ton to an unusually low figure.

WHERE ATTENTION COUNTS

W. Harris Day

How many managers of power plants would be willing to purchase several hundred tons of coal supply to heat scale-covered boiler tubes? None, of course, but that very thing is being done in many plants without the knowledge of the owners, managers or operators.

It is a misconception to regard scale as something produced only by so-called impure feed water, which either carries a visible sediment or is polluted or fouled. On the contrary, scale-forming ingredients, as distinguished from mud, scum, etc., are not visible and are not usually called impurities at all. Water which produces scale in abundance is known as hard water, scale being formed from various minerals dissolved by the water as it trickles over or thru the ground and discoverable only by chemical analysis. Even soft water commonly contains quite a percentage of "hardness."

It is common opinion that water from the Hot Springs of Arkansas is nearly if not quite the purest water found in nature. Yet that water is impregnated with from 5 to 8 grains of "hardness" to the gallon. Water from ordinary sources may contain as high as 40 to 80 grains to the gallon. When water to the extent of hundreds of thousands of gallons is converted into steam, in a few months, in a single boiler, it is realized that the aggregate amount of scale left behind in the boiler must be considerable.

Unless the scale deposit is unusually heavy, it is likely to escape detection, spread as it is over such a large surface, especially on account of the low visibility and accessibility of the tubes being examined. How scale is often underestimated has been illustrated many times.

The superintendent of a manufacturing company in Charlotte, Michigan, thought that the company's boilers were practically clean of scale and in that opinion was supported by the boiler insurance inspector. Yet, as an experiment, one of the boilers was given a thorough mechanical cleaning and was found to contain 450 pounds of scale, or enough to cause the waste of nearly half a ton of coal a day.

A hotel in Jefferson, Mo., thought their boilers quite clean. Nevertheless, it was decided to remove all uncertainty

(Continued on page 36)

Management of Direct Current Machinery

By M. BARRY WATSON
Director of Engineering, Toronto Technical Schools.

DURING the last twenty years, while the distances to which electric power can be transmitted economically have increased by leaps and bounds. the use of alternating current has become very general in most factories and industrial plants. As a result of this, many operating engineers and mechanics have got into the habit of paying practically no attention to their electrical machinery, because there is so little to go wrong with the common types of induction motors. Consequently many of these engineers and maintenance men have forgotten much of what they at one time knew about direct current operation.

There are on the other hand many factories, office buildings, hospitals, schools, etc., where most of the electric power requirements are met by steam generated power, at a cost, when operated in conjuction with heating systems or some manufacturing processes, lower than the lowest rates charged for Hydro-Electric energy transmitted over long distances.

In these local steam plants it is usually found advisable, on account of the demand for elevator service. variable speed motors, etc., to install direct current in preference to alternating current service. Thus the majority of these local plants are designed to generate direct current, and the engineers in charge of them must be conversant with the proper care and maintenance of D. C. generators and motors in order that satisfactory service and long life may result.

It is not the intention of the writer to deal in these articles with the installation, rebuilding, complete overhauling or major repairing of D. C. machinery; but merely to touch on the general care and operation of these machines to the extent to which such equipment must be regularly cared for and maintained by all those in direct charge of their operation, if it is to be continually satisfactory.

The principle upon which all direct current generators or dynamos operate, is that by which a conductor moving in a magnetic field has an electric current generated in it. A motor on the other hand operates on the principle that a conductor carrying a current in a magnetic field tends to move. Thus they are exactly the reverse of each other in action.

Mechanically motors and generators are very similar in construction, in fact they may be identical, or the same machine may be used either as a motor or generator. Therefore these machines will be treated as one, except where some distinction is especially stated.

Cleaning

Cleanliness is the first requisite for the satisfactory operation of electrical machinery of all kinds. In fact if a machine is kept properly cleaned there is little that can go wrong with it at any time.

The armature or rotating part of all large electrical machines is built with numerous air spaces through it, in order that the air circulating through these at high velocity when the machine is running will carry away the heat generated in the windings. Some of the older types or smaller sizes have the armature enclosed with canvas or cord coverings on the ends of the coils.

The air in all power plants has in suspension small particles of dust, as well as moisture and oil vapor, which when drawn through between the windings of an armature may cling to the surfaces of the air passages. In this way the surfaces which are designed to radiate heat to the passing air become well coated with a good heat insulator in the form of a coating of dust. At the same time the size of the openings through which the air is to pass is considerably reduced, thus permitting a much smaller quantity of air to circulate. For these reasons, the heat produced in the windings is not carried away fast enough to keep the machine cool, and the temperature may rise until the electrical insulation becomes destroyed, or even takes fire. The urgent need of keeping the inter-winding spaces clean is thus evident.

A certain amount of cleaning can be done to the accessible parts of a machine by means of a brush or duuster, but the only way in which the interior spaces can be easily reached is by means of currents of dry, clean air. If a supply of compressed air is available, a hose and long nozzle can be used to advantage. Failing a supply of compressed air, a hand bellows with a long nozzle may be used with good effect. In most plants this blowing out should be done at least once a week, or even daily in locations where there is considerable dust in the air.

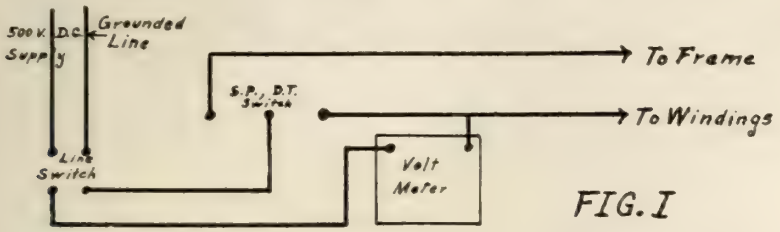
Wiping down should always be done with tightly woven rags, never with cotton waste, as the lint and fibres from the latter are sure to stick to parts of the windings, etc. and collect dust or block the air passages.

Drying

As a general thing the moisture contained in the atmosphere will do no harm to a generator when running, because the temperature of the machine is always higher than that of the surrounding air, thus the moisture in the air will not condense on the machine. If a machine has been stored in a damp location without operating for some time, it will get thoroughly damp throughout the windings. Also electrical machines do sometimes get thoroughly soaked with water, usually due to an accident such as a burst pipe, leaky roof, flood, etc. In such cases the machine must be thoroughly dried out before it is again put in service, because the high leakage of current which would take place through the wet insulation if operated at normal voltage would probably ruin the insulation permanently, or even cause a sufficient current to flow to burn out the machine completely.

If a machine is thoroughly soaked with water, it is best to give it a preliminary drying by means of a draft of hot air if possible. This can sometimes be done by setting up a radiator or

small stove near the machine, and by means of a canvas or tarpaulin cover make a duct for the heated air to go from the radiator through the generator, using some kind of a blower, or even an electric fan, to force the air through. If the machine can be driven by a belt, or another motor, during this process, it will assist in speeding up the drying, but in this case the brushes should be removed, or the field circuit opened, to prevent high voltages or large currents being generated. Machines can be thoroughly dried out in this manner, but the "electrical method" is generally quicker for the final drying. Small machines can sometimes be placed in a hot air duct and dried out quite quickly there.



Wiring for Insulation Tests.

The "electrical method" may be used for machines which are very damp, but not thoroughly soaked. In the case of a generator, the machine should be driven, not over rated speed, with the armature short-circuited beyond the am-meters, and the shunt field rheostat adjusted till the am-meters show not over 125% of full load current. It may be necessary on some types of machines to short circuit, or even cut out of the armature circuit, the series and commuting pole windings in order to keep the current flowing at a low enough value at full speed.

In the case of a motor, the armature may be connected to the line in series with an am-meter and a resistance which can be adjusted to allow not over 125% of full load current to flow. Care should be taken however to see that the resistance is connected to the ungrounded side of the line, to prevent high voltages between the windings and the frame of the machine. In the same manner the field coils may be connected through a resistance in the ungrounded side of the line to normal supply voltage. If the field coils are normally connected in series, it is worth while to reconnect them in parallel to prevent excessive voltages to the frame. The voltage across any field coil should never be more, and generally less than normal voltage across that coil when operating. The armature current can be allowed to flow in the series and commutating pole coils as it assists in drying them out at the same time. The load should be removed from a motor while drying and it should be allowed to revolve if it will.

With the currents mentioned above flowing, the coils should soon warm up to 70 degrees Centigrade or 160 degrees Fahrenheit, and their temperature should not be allowed to exceed 80 deg. C. or 175 deg. F. as the insulation is easily injured by excessive heat, especially while damp.

The temperature rise of the windings can be found electrically, but this method is generally too complicated for the average engineer to bother with. It is generally easier to shut down the machine at intervals and use a mercury thermometer with the divisions on the glass stem. The bulb of such a thermometer can be tucked in between some of the turns of the windings and packed with rags or other poor conductors of heat and left there until the mercury ceases to rise in the stem, this will be a matter of a few minutes, then the temperature can be read. It is well to remember that in closely wound coils the temperature of the inner turns is probably ten degrees or more higher than the outer ones which are in contact with the air.

While it is impossible to determine exactly to what extent drying out has been accomplished, the progress of the process may be watched with sufficient accuracy by those fortunate to have the use of a "Megger" or high resistance meter. There is no standard of insulation resistance for electrical machines, because different makes and sizes of machines give different values of insulation resistance. Previous to drying out a machine, the resistance to the frame from the windings will be comparatively low, this value will gradually increase however as the drying proceeds. The machine can be considered as dry when the insulation resistance ceases to rise with continued heating. The insulation of the field to frame and of the armature to frame should always be tested separately, this requires the disconnection of these parts during the tests. The time required for drying the field coils is generally longer than that required for the armature, on account of the closeness and thickness of the winding on the former.

Insulation tests can be made with a Voltmeter where direct current voltage is obtainable. Connections should be made as in Figure 1, taking care that the frame of the machine is never connected to the undergrounded side of line. A 110 volt circuit may first be used as a trial and if found that the insulation resistance is too high to give any reading when the voltmeter is connected in series with the insulation, as when the double throw switch in the diagram is thrown to the left, it will be safe to use a 550 volt D. C. circuit and a voltmeter reading to 600 volts.

In using the above connections with a Volt meter, the switch is first thrown to the right so that full line voltage is read. it is then thrown to the left, placing the insulation in series with the voltmeter, and the reading of the meter taken. The insulation resistance can be calculated by using the following formula:—

$$R = \frac{r\,(V-v)}{v}$$

Where V = Line Voltage,
v = Voltage reading with insulation in series with voltmeter.
r = Resistance of Voltmeter in Ohms. (This is generally marked on the nameplate, or inside the lid of instrument box.)
and R = Resistance of insulation.

It may require only a few hours running in this way to dry out a machine, or it may be a matter of days or weeks. Without any of the above facilities for noting the progress of the drying out process, it is better to err on the safe side and continue the drying too long. Large machines take longer than small ones, so it is largely a matter of judgment on the part of the operator as to when it is safe to put the machine in operation again without doing it any harm.

Oil in the Windings

Whether condensed from oil vapor in the air, or whether spilled or splashed on the windings of a machine, oil is most harmful. Primarily, if allowed to soak into the windings, it may rot the insulation, and render it both electrically and mechanically useless. On the other hand it holds the dust which it catches, making it almost impossible to remove, thus causing heating.

Care should therefore be taken to prevent the overflow or creeping of oil from the bearings to the windings.

If freshly spilled on the windings, oil can be removed by washing with benzine or gasoline, but these must be allowed to dry thoroughly before the machine is again operated, as a spark at the brushes might easily set fire to any vapor coming from the windings, and cause much damage.

(To be Continued)

TO CHARGE BATTERIES

Question:—I have a 110 volt direct current lighting circuit from which I want to charge automobile storage batteries. Please explain with figures and sketch a wiring circuit in which I can use 40 watt incandescent lamps as resistance to get the correct voltage and current to charge one or more auto storage batteries at one time. What is the discharge voltage and current capacity of a common auto storage battery?

Answer:—If it is desired to charge a small auto starter battery from a 110 V. D C. Main, using electric light

bulbs as a resistance, it would not be economical to use the Tungsten or Nitrogen lamps, as their current consumption is so low that it would be necessary to use such large powered lamps, and so many of them that the cost would be much too high.

The carbon filament lamp consumes many times more current than either of the above mentioned types. A carbon filament lamp consumes about ½ for a lamp of 16 Candle Power at 110 volts and ampere for 32 C. P. at that voltage.

The usual charging rate for auto-starter batteries varies considerably, depending upon the voltage of the battery, and upon the size and number of plates per cell.

These limits usually run as follows:—
3 Amps on a 24 Volt System.
5 Amps on a 12 Volt System.
10 Amps on a 6 Volt System.

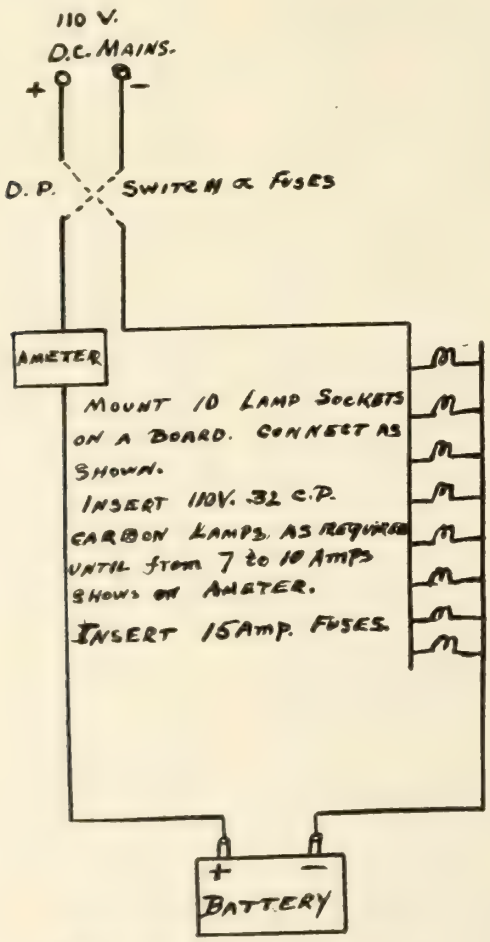
These are the charging rates employed at the beginning of the charge but towards the end of the charge, when rapid evolution of Hydrogen is taking place, the above charging rates must be reduced, or permanent damage will result to the battery.

The nominal voltage of each cell in a storage battery is 2 volts. Each cell in the battery being connected in series, and their voltages thereby being added. It is therefore always possible to tell the voltage of the battery by counting the number of cells and multiplying by two.

This nominal voltage of 2 volts per cell is only whilst the cell is an open circuit, and not delivering energy, or discharging. When the cell is discharging the voltage rapidly falls below 2 volts. This fall again depends upon the rate at which the cell is being discharged, and a limit is rigidly fixed by all manufacturers for the fall of voltage, below which the cell must not be worked. This limit is fixed between 1.65 volts to 1.80 volts depending whether the cell is being discharged at a low rate or at a high rate.

The sketch below will show a cheaply made arrangement for charging an Auto-Starter battery from the D. C. Mains of 110 volts. A more costly and more workmanlike arrangement could be made by placing switches in each separate lamp circuit, but a similar result can be obtained by simply unscrewing the bulb from the socket, whenever the current from a particular lamp is not required.

This arrangement is merely a method of connecting a battery in series with a number of lamps in parallel. Supposing each lamp consumes 1 ampere, by the mere addition of lamps, more current will be allowed to flow through the circuit.



Wiring diagram for battery charging.

WHERE ATTENTION COUNTS

(Continued from page 33)

by cleaning the boilers thoroughly, with the result that one boiler gave up 300 lbs., another 250 lbs., and a third 420 lbs. of scale.

In a tannery in Newport, Tenn., as much as 1000 lbs. of scale were taken out of a single boiler, in spite of the inspector's pronounced opinion that the boiler was comparatively clean. When the result of the cleaning was observed, "We were never more astonished," were the words of one of the officials of the company.

In some plants it is sought to avoid the labor of cleaning by injecting certain chemicals into the boilers and then blowing the boilers down or otherwise removing the scale loosened by the chemicals. These vary all the way from harmless, innocuous substances to the most corrosive combinations. Some think that the right combination of chemicals has quite a bearing on the greater ease or the frequency of boiler cleaning operations; but they are decidedly not a substitute therefor. In the words of one of our leading boiler manufacturers, "for, though a rapid circulation of chemicals will change its character, the most certain cure is periodical inspection and mechanical cleaning."

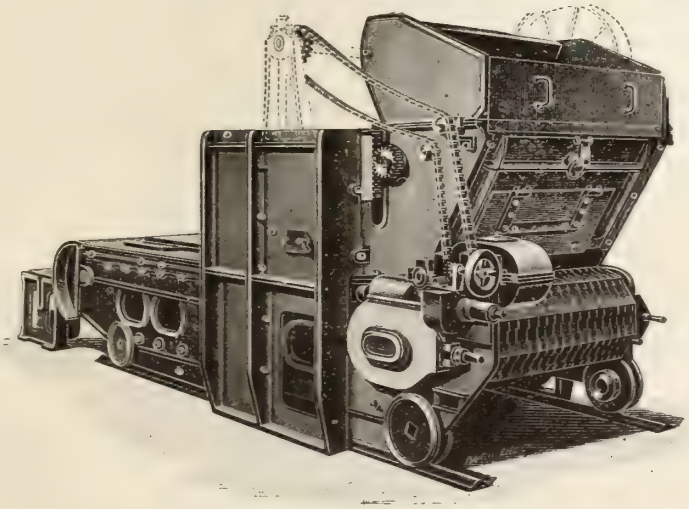
The evidence of falling scale following such a treatment is no test for thorough cleaning. It is likely that the same test might be applied with similar results, without any treatment at all, by simply turning the force of a good stream into the boilers. This test has misled many an engineer into a false feeling of satisfaction regarding the condition of his boilers.

The rapidity of scale deposit varies of course in different plants, but a rate of 1/16 inch in from two to six months is considered very moderate. Such a thickness, according to experiments conducted by leading experimental stations and research laboratories, indicates a fuel waste of about 12% or 13%, depending somewhat upon the character and density of the scale. An interesting example of the better steaming results accomplished by cleaning the boiler tubes occurred a number of years ago.

A certain coal company obtained contracts to supply coal to a number of plants. After a time, complaints began to arrive to the effect that subsequent deliveries of coal were not so good as the first, that the boilers did not steam as easily as before nor as economically. To meet this objection, the company kept impressing the importance of clean tubes upon its customers and, in a short time, secured the adoption of thorough cleaning methods by most of them. The complaints about coal stopped as soon as the effects of the cleaning were felt.

Another company, in order to secure a coal contract, actually cleaned the boiler tubes of its prospective customer. First of all, a competitor's coal was tried out for a period of two weeks. Then its own coal was to be tried out for the

"B & W"
MECHANICAL CHAIN GRATE STOKER



YOU CAN SAVE MONEY with a BABCOCK & WILCOX Chain Grate Stoker because you actually burn less good coal than by any other method of firing. Even if you have but 100 Boiler Horse Power it pays because of the coal saved.

You can burn cheaper coal than you will handfire successfully as these Stokers are particularly adapted to burn the smaller and poorer grades.

With handfiring it is difficult to get firemen to take the necessary care and to give the constant attention necessary for complete and smokeless combustion. With the B. & W. Chain Grate Stoker the attendant is not required to work so hard or to expose himself continually to the heat of the fire, and he can apply himself to getting economy.

A good fireman can handfire a 200 H. P. Boiler at ordinary rating, but only the skilled and better-paid men can handle overloads. One man can shovel into the hopper of the B. & W. Chain Grate Stokers all the coal necessary for 1,000 Boiler H. P. or he can attend to 2,500 to 5,000 Boiler H. P. where the coal is fed to the hoppers automatically. Over ratings are obtained with little or no extra effort on the part of the attendants.

Combustion rates may be secured with a B. & W. Chain Grate Stoker which cannot be approached by hand firing methods. The increase in efficiency is the result of the even and continuous firing, the constant air supply, complete absence of the necessity of working the fires and the fact that the coal is burned according to the natural laws of combustion.

WE SHALL BE VERY GLAD OF AN OPPORTUNITY TO DISCUSS YOUR COMBUSTION PROBLEMS WITH YOU

(Continued from page 36)

same period. But between the tests, the company had a man go into the power plant and, with the aid of a boiler cleaner, remove scale from the tubes. The results from the second test were so much better than those from the first that the contract was secured easily, although the condition of the boilers probably had far more effect than the grade of coal.

Reference is here made to a principle which has proved particularly effective in removing scale, not only from badly encrusted boilers, but from boilers which were thought not to require cleaning. Vibration of metal tubes to dislodge scale is partly an adaptation of an old method. Before the tube cleaners were invented, it used to be customary to insert an iron bar in o or between the tubes and with it knock or scrape off such scale as could be reached. Of course it was not a thorough method and it was hard for the workman, but it was better than nothing.

Today the principle is employed in a decidedly different manner. Instead of hand cleaning, there are mechanical cleaners, and, in place of heavy, intermittent blows, there is a broken up series of light but rapid taps, which play impartially on every bit of the tube walls. All the scale, no matter how tough or tightly adhering to the tube is removed without difficulty by taking advantage of the contrasting nature of scale and metal, the extreme elasticity of the one and the rigidity of the other.

An especial advantage of the vibratory principle is that it can be employed in either water tube or return tubular boilers, to remove encrustation from either the inside or the outside of the tubes, and hard-caked soot as well as scale.

Transfer of heat without loss from the furnace to the water in the boilers is just as important as correct combustion. Yet, ordinarily, where combustion is concerned, thousands of dollars are spent without a qualm for the sake of securing a possible ten or twenty per cent. return on the investment, whereas the problem of transmission is relegated largely to the mechanic in charge of the boiler room; and even his hands are tied within very rigid limits.

Scale wastes affect heat transmission. It is not improbable that very little attention by the management to this phase of power production might well show savings unbelievably large at a cost which would be by comparison absolutely insignificant. The prevention of scale wastes should interest the management as much as if not more than the engineer, partly because the losses are great, partly because they are easily preventable.

REDUCING BEARING FRICTION

The proper lubrication of all bearings, whether they are roll necks or engine slides, seems not to be so well understood by the average run of superintendents as might be the case, as many seem to think that all that is necessary is to supply the machine with grease or oil and let it go at that, the men accepting all wear on journals as an evil which cannot be avoided. It is true that wear on any bearing and journal cannot be prevented, but it is also true that it can be minimized to the lowest possible extent by using the right type of lubricant for differing sets of working conditions among various classes of machinery.

GRAPHITE AS A LUBRICANT

It is well known among lubrication experts, but not by the average run of mill and factory officials, that the consistency of any grease or oil has to be suitable to the weight and rapidity of motion of different machine parts, a lightly constructed machine, such as a watch, requiring a very thin oil to enable it to run. On the other hand, a thin oil proves to be unsatisfactory for roll and pinion necks, as it is squeezed out by their weight before it can get in efficient work. Suet and water mixture is like a thin oil, it being very costly in the end as regards the length of time that rolls can be operated before they are thrown away in the scrap heap. Graphite works on an entirely different principle from oil, and it is the best lubricant of all for heavy machinery in rolling mills. Metals are never smooth.

OBITUARY

Joseph P. Rogers

J. P. Rogers, director of the Queen City Oil Co., died last week at his home in Toronto. The late Mr. Rogers was born in King Township, North York, October 17, 1856, and received his early education in Newmarket High School and Earlham College, Richmond, Indiana. He came to Toronto in 1876, and shortly afterward entered into business with his father, the late Samuel Rogers, and his brother, Mr. A. S. Rogers, under the firm name of Samuel Rogers and Company, and later under the name of the Queen City Oil Company Ltd. He was manager of the lubricating department at the time of his death, and was also a director of the Imperial Oil Co.

Columbia Recording Thermometers now made with the New Time Punch!

After all, efficiency is not magic—nor is it an idealistic fantasy; it is first of all, common business sense. Secondly, it is intelligent supervision of men and methods.

You cannot hope for intelligent supervision if you rely on "rule of thumb" methods; you must have actual knowledge of operation, of results, of existing conditions.

Such is the function of the "Columbia" Recording Thermometer, it is an efficiency instrument, for it

ELIMINATES GUESSWORK

The "Columbia" Recording Thermometer furnishes mechanically written temperature records of any heat-treating process—of any operation where temperature study is important.

PURCHASE THEM IN TORONTO

In order to meet the steadily increasing demand in Canada, we have equipped a Branch Supply House at 67-69 Frederick Street, Toronto. From the generous stock of S. & B. Equipment carried, we can give our Canadian customers the service they are entitled to as well as full information regarding Prices, Technical Data, Deliveries, etc.

THE Schaeffer & Budenberg MFG. CO.

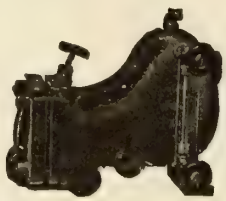
HINTS TO BUYERS

GODFREY CONVEYORS
Save Time, Labor and Money

In unloading cars and handling coal, coke, ashes, sand, gravel and similar materials.

Send for descriptive catalogue No. B-1.

M. A. KENNEDY, Limited
106-110 Richmond St. West, Toronto, Canada.
GODFREY CONVEYOR COMPANY
124-147 Thirteenth St. - Elkhart, Indiana, U.S.A.

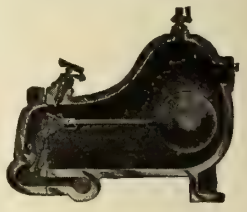


McDaniel Improved
STEAM TRAP
FOR HIGH OR LOW PRESSURE

Steam can't blow through. They have large discharge valves and cannot be flooded from sudden flushes of water.

May We Send One for Trial

Reducing Valves, Pump Governors, Relief Valves, Exhaust Pipe Heads, Ejectors and Steam Separators.



Send for Catalogue

THE GARTH COMPANY
26 Craig Street - MONTREAL, CAN.
WATSON & McDANIEL CO.
No. 146 N. 7th St., PHILADELPHIA, Pa.

Kingsbury Thrust Bearings
Made in Canada

Our pivoted-block Thrust Bearings are a complete solution of all thrust-bearing problems in hydro-electric units, steam turbines, ships' propeller shafts, centrifugal pumps, and similar work involving heavy loads and high or low speed.

Maximum Durability and Reliability.
Lowest possible Friction.
No limit to loads or speeds.
Protected by numerous Canadian Patents. Complete manufacturing facilities in Canada, insuring prompt deliveries and service.
Send for Catalogue.

Kingsbury Machine Works
Frankford, Philadelphia, Pa.

"Pop Off" Steam Carries Ashes Away

"Into the hole and away they go" describes ash removal with a Green Steam Jet System. At the Kewanee Boiler Co., they use "Pop off" waste steam to do the work.

Write to Dept. X for descriptive literature.

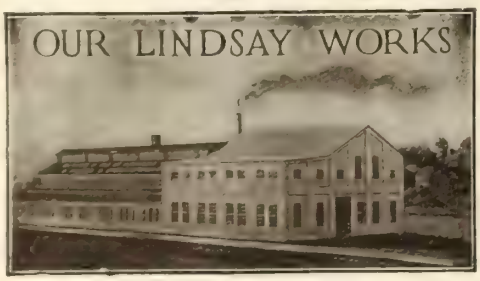
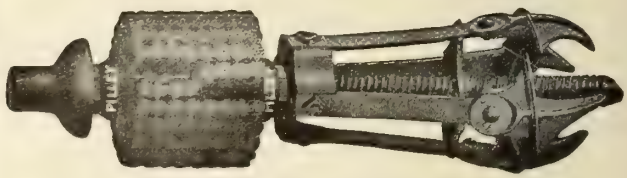
Water Turbines, Hydraulic Governors, Centrifugal Pumps



Boving Hydraulic & Engineering Co., Limited
Lindsay, Ontario

The Simplest and best cleaner on the market is



PILLEY'S

Combination Flue Brush and Scraper.
Guaranteed not to break or the wires to pull out or lay over. A simple turn of the hand adjusts it to the tube, and the brush removes what the scraper loosens.
For sale by leading Canadian jobbers.
Manufactured by
PILLEY PACKING AND FLUE BRUSH MFG. CO.
623 South Third Street - - - St. Louis, Mo.
Eastern Office: 71 Fulton St., New York.

Better Protection For Engine or Transformer

The De Laval Oil Purifier insures your engines or transformers against damage resulting from keeping inefficient oil in service. Continued use of the De Laval maintains the original characteristics of the oil so that it may be used indefinitely. Thus a saving of oil is made which will in a short time pay for the Purifier.

De Laval Oil Purifiers

are furnished as stationary units to be connected into the turbine or Diesel lubricating system, or piped up to transformers. A portable transformer oil purifier is furnished for the sub-station service. This portable unit may also be used for cleaning up batches of lubricating oil.

De Laval Oil Purifiers are made in sizes to fit every plant. **Write for Bulletin No. 105, which tells how they will save money for you.**

POWER HOUSE BUYERS' DIRECTORY

If what you want is not listed here write us, and we will tell you where to get it. Let us suggest that you consult also the advertisers' index facing the inside back cover, after having secured advertisers' names from this directory. The information you desire may be found in the advertising pages. This department is maintained for the benefit and convenience of our readers. The insertion of our advertisers' names under proper headings is gladly undertaken, but does not become part of an advertising contract. Readers are requested to advise the publishers regarding any equipment that they are buying and that is not listed.

No More Joints

In a furnace lining, trouble usually starts in the joints —bricks fall out and mortar crumbles. **But there are NO JOINTS in**

PLIBRICO JOINTLESS FURNACE LINING

PLIBRICO, applied when plastic, when baked and properly vitrified forms arches, baffles, side walls and bridge walls—all parts of the boiler setting—that are hard, smooth, jointless, resistant to heat up to 3100° F., and outlast ordinary fire brick from two to four times.

If you want service, permanent settings that are air and gas tight, **eliminate the joints.** Use PLIBRICO.

Send for our book N-61 on "Modern Furnace Building." Our nearest representative will make a study of your furnace problems, **free.** Ask to have him call.

PLIBRICO is delivered only in steel containers of distinctive appearance as shown below.

DISTRIBUTORS:—Beveridge Supply Co., Ltd., Montreal, Que.; Shell Bar Boico Supply Co., Ltd., Toronto, Ont.; Evans, Coleman & Evans, Vancouver, B. C.; Winnipeg Supply & Fuel Co., Winnipeg, Man.; Gorman's Ltd., Calgary, Alta.

CO. LTD.

COAL STRIKE

This sign brings up the question of Fuel Economy.

Users of **PLIBRICO** Jointless Fire Brick and of our other Fuel Savers can now contemplate a nice reserve effected through use of these lines. This will enable them to meet emergencies and tide over present difficult times. **PLIBRICO** specially suited for Oil Burning Furnaces.

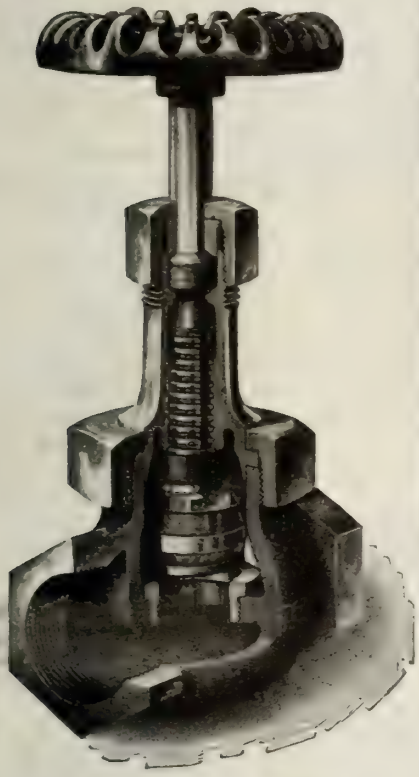
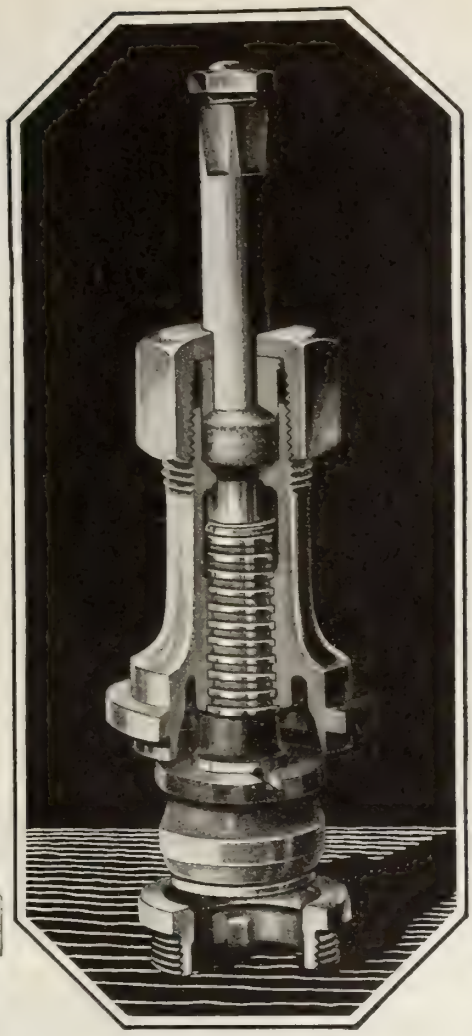
"RENEWO"

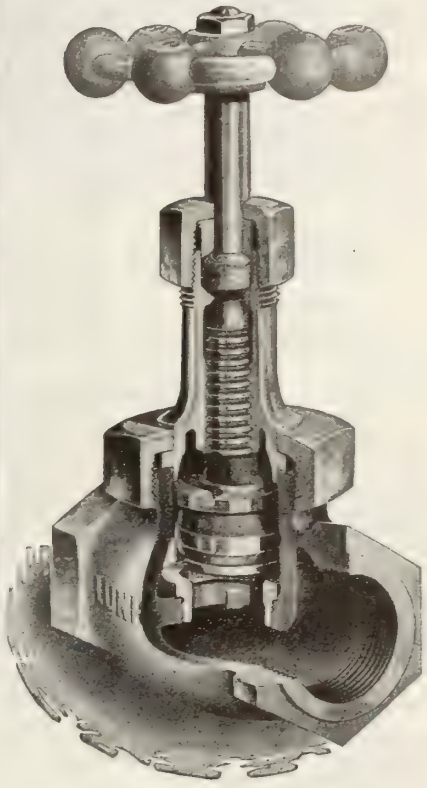
(Bronze Body)
Fig. 73, Medium Pattern
for 200 lbs. W.S.P
Fig. 16, Extra Heavy for 300 lbs.

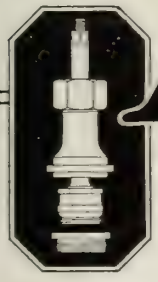




"FERRENEWO"

(Ferrous Body)
Fig. 1021
for pressures up to
150 pounds





Interchangeable

and renewable as well, and this applies to all wearing or bearing parts of Lunkenheimer "Renewo" and "Ferrenewo" valves.

Standardization throughout a plant, with its resultant economies is easily accomplished with the "Renewo-Ferrenewo" combination—"Renewo" Valves for the high pressure lines and "Ferrenewo" for the low pressure lines, with only one set of repair parts necessary to meet any emergency. Both types also embody the well-known Lunkenheimer Regrinding seat feature.

Familiarize yourself with the manifold advantages of the "Renewo-Ferrenewo" combination. It pays.

Descriptive literature sent on request.

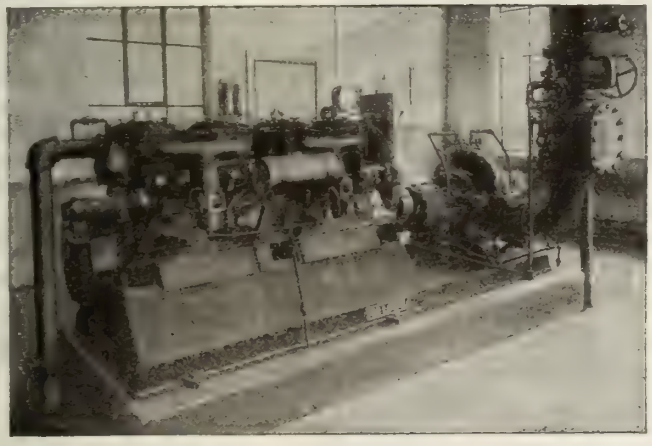
A New Boiler Equipment is Your Best Investment

The heart of your business is your power plant. If your heart isn't sound you can't win in the business race. New Boilers of modern design, now, from us, will show splendid economies over old, wasteful equipment. We make all types. Prices low.

Engineering and Machine Works of Canada, Limited

ST. CATHARINES, ONT.

Eastern Sales Offices:
HALL MACHINERY CO., Sherbrooke, Que., and Birks Bldg., Montreal



One of two DeLaval centrifugal pumps driven by gasoline engines; installed for the City of Pembroke, Ont.; 900 gal. per min. against 349 ft. head at 1,400 r.p.m.

Gasoline Engine Driven Centrifugal Pumps For Water Works Service

THE high thermal efficiency of internal combustion engines, the small amount of attention required in their operation, and the small building space and light foundations required, recommend them as a most economical drive for pumps under certain conditions, particularly for standby or reserve plants.

The photograph shows one of two De Laval units recently installed for the City of Pembroke, Ontario. In this unit, the numerous pump valves, packings, etc., found in reciprocating pumps, are eliminated, so that attention is rarely required. Such parts as are subject to wear are made on an interchangeable limit-gage basis, and worn parts can be replaced easily by new parts ordered from the factory. The high efficiency of De Laval pumps results in a marked saving of fuel.

If you will state your pumping requirements fully, our engineers will advise you as to the best type of equipment for your conditions. **Ask for special publication W100.**

SUPERHEAT—

The Logical Step toward Economy—

$$E = \frac{T_1 - T_2}{T_1}$$

In this well known formula for the theoretical efficiency of a heat engine, the temperature of the steam coming to the engine or T1, and the temperature of the heat rejected or T2, can never be such as to make any steam engine 100% efficient.

By compounding, the value of T2 is decreased, and with T1 constant, the efficiency will be increased. T2 may be further decreased by condensing.

By increasing boiler pressures, T1 is increased and therefore higher efficiency results. However, as pressures are increased, for a relatively slow gain in T1, practical difficulties are encountered in boiler design and maintenance.

The most logical and practical means for increasing the efficiency of an engine is to increase the value of T1 by superheating. Furthermore, the use of superheated steam improves the operation of all parts of a power plant.

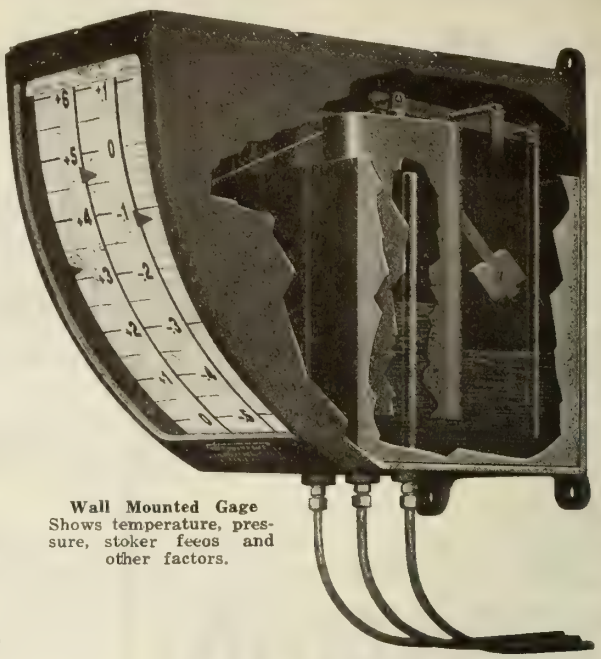
A Gage of Great Utility

The application of the Bailey Multi-Pointer Gage is not limited to the boiler room. It is equally effective in turbine, condenser and pump operation.

In conjunction with the Bailey Boiler Meter, which records all the important operating conditions, this modern instrument completes the information required to maintain each boiler furnace at the highest possible efficiency.

The instrument may be mounted on the boiler front irrespective of poor illumination as the bright dial may be read at a distance.

Instead of reading draft in various boiler passes, ash pit pressure, steam temperature, fan, engine or stoker speed on many individual instruments—read all these factors from one instrument, the



Wall Mounted Gage
Shows temperature, pressure, stoker feeds and other factors.

Bailey Multi-Pointer Gage

May we explain more fully how it will help to promote economy in your power plant?

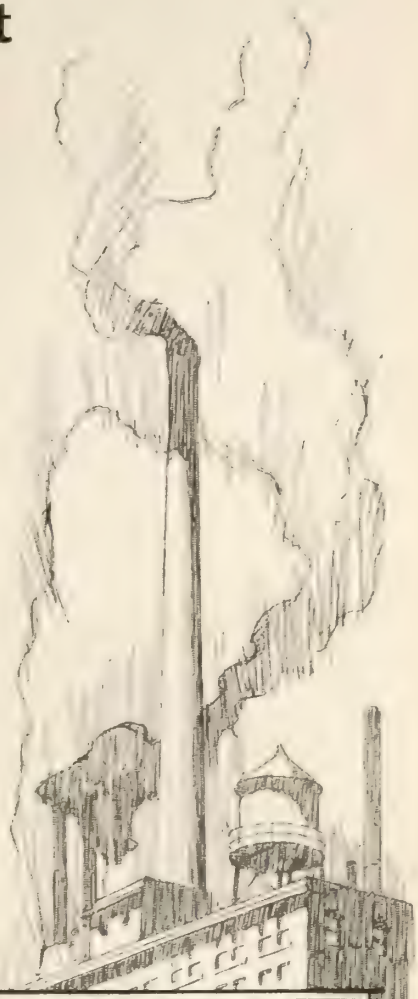
Drain Condensation and Put It to Work
Reduce Your Fuel Bills 15 per cent



Is the condensation in your steam lines an asset or a liability?

You can put the condensation to work—and lower your fuel costs by returning it direct to your power plant and using it for boiler feeding.

The A B C Detroit System returns the condensation to boilers at high temperature—ready to burst into steam—and eliminates steam pumps which fail to operate when the temperature of condensation is above 212 degrees.

Draining steam lines and steam heated machinery of all condensation as it forms, the A B C Detroit System keeps this apparatus at top heat—at highest efficiency—and speeds up production.

Let us send you complete information regarding the A B C Detroit System and refer you to plants in your locality which have lowered their fuel costs an average of 15 per cent by returning condensation direct to boilers.

MORRISON

Pressure Recording GAUGES

"Here's How They Save"

YOU'RE a practical man but have you ever stopped to figure just how much fuel is wasted through varying pressure?

You know, of course, these interruptions cause a fuel loss, so does the boss—and right there is where the **Morrison Pressure Recording Gauge** benefits both you and the boss.

No doubt you take a pride in maintaining an even pressure all the time—every honest-to-goodness fireman does that. Well, isn't it more satisfactory to you to know that your pressures are accurately recorded, and won't the boss feel better when he can be sure that he is getting a maintained pressure without unnecessary fuel loss?

Some of our lines:

- Stop Valves
- Check Valves
- Reducing Valves
- Steam Traps
- Injectors
- Ejectors
- Inspirators
- Vacuum Gauges
- Lubricators
- Steam Whistles
- Engine Indicators
- Pipe Fittings, Etc.

Every installation is a demonstration of merit.

POWER HOUSE

A semi-monthly paper devoted to the Generation, Transmission, and Application of Steam, Gas, Electric, Air and Water Power; the operation of Refrigerating Machinery; Heating and Ventilating Equipment.

Published by The MacLean Publishing Company, Limited, 143-153 University Avenue, Toronto
MONTREAL, WINNIPEG, VANCOUVER — LONDON, ENG.: 88 Fleet Street, E.C. — NEW YORK, BOSTON, CHICAGO

Vol. XV.—No. 10 — Publication Office, Toronto—May 20, 1922 — Published Semi-Monthly Canada, $2; U.S. $2.50 a year

There's a Jenkins Valve for every service. Made of brass, iron and cast steel for steam, water, air, gas, oil and other fluids and vapors.

Here's The Perfect Valve Disc!

A Jenkins Disc—manufactured from high grade rubber and special ingredients, carefully selected and compounded and vulcanized under hydraulic pressure.

A disc that, because of its great flexibility, always forms a perfect contact with the seat giving the valve unlimited life and usefulness under the most severe usage conditions.

While it is important that genuine Jenkins Valves be used where trouble-free service is essential this service can only be assured by the use of Jenkins Discs.

Avoid imitations. Ask for Jenkins Discs by name. At Supply Houses everywhere.

UNITED

5 Retort RILEY STOKERS installed under 487 H. P., G. & McC. boilers.
Smith, Hinchman & Grylls, Consulting Engineers, Detroit.

More Steam at Lower Operating Cost

THE PROBLEM.

At the plant of Hiram Walker & Sons, Ltd., Walkerville, Ontario, more steam was required. Their boiler room contained 10—125 H.P. boilers. These boilers were economically fired but the plant layout in general was inefficient.

THE SOLUTION.

They replaced these *10* boilers with *3* of 487 H. P., fired by Riley Stokers which now gives them ample steam capacity. Although the normal boiler H.P. is increased but little the *actual* capacity is about three times greater because the Riley Stokers will operate the boilers up to 250% of rating or more. *When the above picture was taken two of the boilers were making 200% of rating.*

THE RESULT.

Greatly increased capacity with a *reduction in operating expenses.* The improved power plant layout with automatic coal and ash handling equipment and Riley stokered boilers has made possible a reduction in labor from 8 men to 2 men per shift. This saving in labor alone amounts to nearly $100 per day.

Find out what the Riley can do for you.

Files Hand Stokers Getting Results

PANTHER RUBBER COMPANY, LIMITED

GENERAL OFFICES AND FACTORIES
SHERBROOKE, QUE.

SHERBROOKE, CANADA September 23, 1921.

The Waterous Engine Works Co. Ltd.,
Brantford, Ont.

Gentlemen:

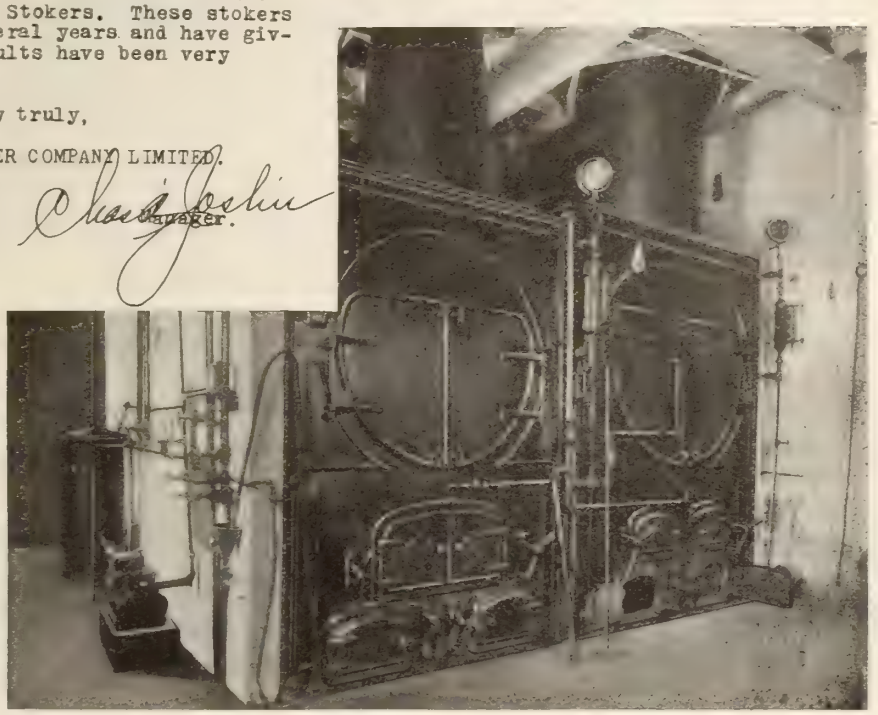
In reply to your letter of the 8th instant we have in our plant the Files Stokers. These stokers have been in operation for several years and have given excellent service. The results have been very satisfactory.

Yours very truly,

PANTHER RUBBER COMPANY LIMITED.

Manager.

CAJ/RMK



It is the uniform excellent service and general satisfaction that have caused progressive men to select **Files Stokers.** These are typical of the more complete data we have compiled:

One installation (3,600 H.P.) saved enough coal to pay for their stoker investment in five months.

A Files installation operated for five months continuously at an average rating of 223%—doubling their steam output.

Files stokers increased efficiency of one plant sufficiently high to warrant discontinuance of two out of eight boilers.

Here is a ready explanation of these achievements:—

1. **Complete volatilization of green coal, causing intensified combustion and smoke dissemination.**
2. **Correct distribution and proper proportion of air according to load carried.**
3. **Fuel bed continuously kept clean, uniform and rich.**

Given the opportunity we will be glad to present these facts for your complete satisfaction.

The Waterous Engine Works Company, Ltd.

Brantford, Ontario

"Dart" Union

BRONZE TO BRONZE **PIPE COUPLINGS** AT THE JOINTS

Clamp Down on Steam Waste !

Guard your steam as you would your money. Don't let it get away before it gives you every possible ounce of value.

It is an easy matter to make your steam behave if your pump is equipped with the well-known

Fisher Pump Governor

(Type 1.)

For over forty years it has led the field in continuous, dependable service. Many of the "old timers" are still in use.

Made of the highest grade materials—the Fisher Governor will last a life-time. Tested, approved and listed as standard by National Underwriter's laboratories.

Its simple, sturdy construction enables it to function perfectly with minimum attention and repair.

Valve and seats are made of our special formula, hard-phosphor bronze, which resists corrosion and wire-drawing.

When planning new equipment let us quote you prices. Write for illustrated catalog.

MACLEAN
UNDER-FEED STOKERS

This sturdily constructed stoker reduces coal consumption and puts an end to power interruptions.

The simplicity of operation adapts it to plants of practically every size. It responds automatically to sudden demands for steam; and a constant uniform steam pressure is carried regardless of varying loads on the boilers.

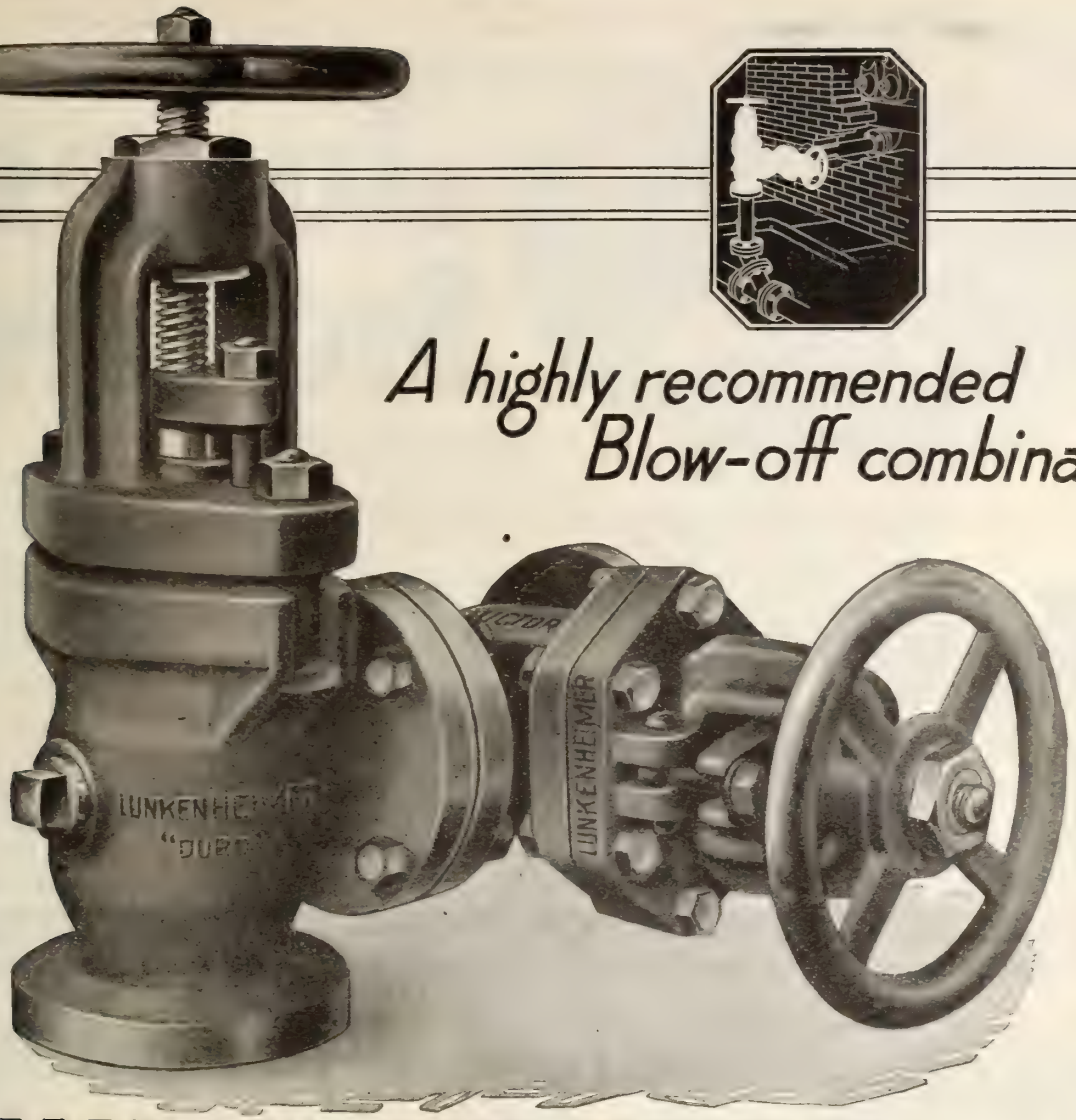
No siftings of unburned coal fall to the ash pit because there are no grates. Small cost of upkeep because no moving parts are in contact with the fire.

The saving in coal will quickly pay for a MACLEAN STOKER. If you operate a steam boiler you should not be without one. Write us for particulars.

MacLean Underfeed Stoker Company, Limited

95-97 King St. E., Toronto, Ontario

A highly recommended Blow-off combination



"DURO" Fig. 897.

"VICTOR" Fig. 892.

LUNKENHEIMER
Blow-off Valves

Remain tight in service, prevent waste through boiler blow-off lines, and thereby turn to a profit the losses caused by leakage which frequently occurs at this point.

In Lunkenheimer Blow-off Valves the water is released gradually due to the peculiar construction of the seat and disc. This virtually makes them safety devices since they eliminate the dangers incident to undue agitation within the boiler or severe shock in the discharge line which result when blow-off valves are opened suddenly.

Lunkenheimer design and construction reduces wear to a minimum. When wear does appear the repair of the parts affected is easily accomplished and when a part is worn beyond repair it can be renewed.

The installation of Lunkenheimer Blow-off Valves is the solution of your boiler blow-off problem. Why not get the facts first hand?

Descriptive literature on request.

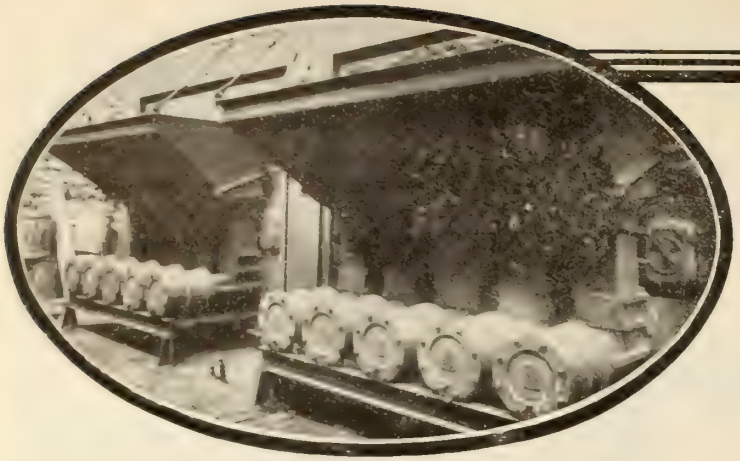
"America's Best since 1862"



Jones Stokers

It's the cost of stoker service that counts—

The Canadian Stoker

Jones Stokers are made in Canada by Canadians and are sold for Canadian money at par. Through special arrangement the extensive engineering resources of the Under-Feed Stoker Co of America are made available for Canadian power users. Thus, this strictly Canadian stoker is backed by world-wide experience and unequalled engineering ability

THERE is just one sound reason for installing mechanical stokers—because they pay dividends; are money makers.

But in spite of the fact that stokers are not an item of expense but a means of saving a few big power users make the mistake of selecting them on a basis of first cost.

You install stokers to save coal—the stoker that will save the most in proportion to its first cost, will, of course, yield the greatest dividend.

You install stokers to increase plant capacity—the stoker that will carry heaviest overloads endlessly, will best fill this requirement, regardless of its cost. You will find that stoker is the Jones "A-C."

You install stokers to save labor—not alone operating labor, but repair labor as well—the stoker that functions automatically and requires least repairs is the best investment.

The Jones "A-C" costs no more than other stokers intended for the same service—and it pays a greater dividend in countless ways.

The Jones "A-C" catalog explains how the Jones Stoker pays for itself—then pays dividends. Write for your copy.

Bailey Weir Meter

Built Differently—and Better

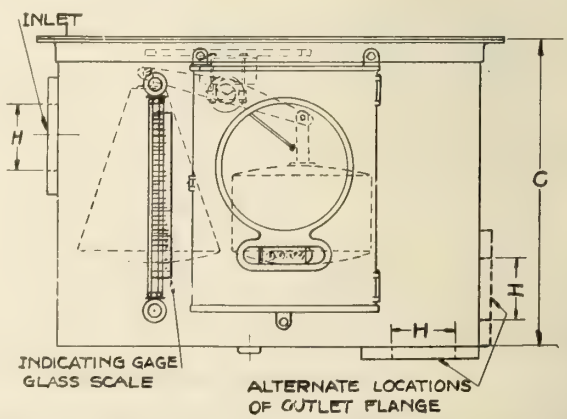
Insuring Freedom from Error

THE accuracy of the V-notch has never been questioned. The standard V-notch is employed in the construction of Bailey Weir Meters, but the construction involves a different principle in recording and integrating the flow than is used in any other meter. There are no cams, springs, racks, gears, roller guides or flexible connections used in the Bailey Weir Meter.

ANYONE who has had experience in calibrating V-Notch Weir meters or doing any hook gauge work in connection with them knows of the great difficulty of accurately determining the true zero level. An error of a few hundredths of an inch at this point may mean as much as 5% error in the flow reading at the higher rates. Any type of recorder where the operating float rises and falls directly with the level of the liquid is open to this serious error.

The design of this Bailey Weir Meter entirely obviates the possibility of such an error, for the relative position of the two displacing members is made right by construction and no changes can possibly take place to alter it.

Bulletin No. 60 explains the advantages of Bailey Weir Meters—write to-day.

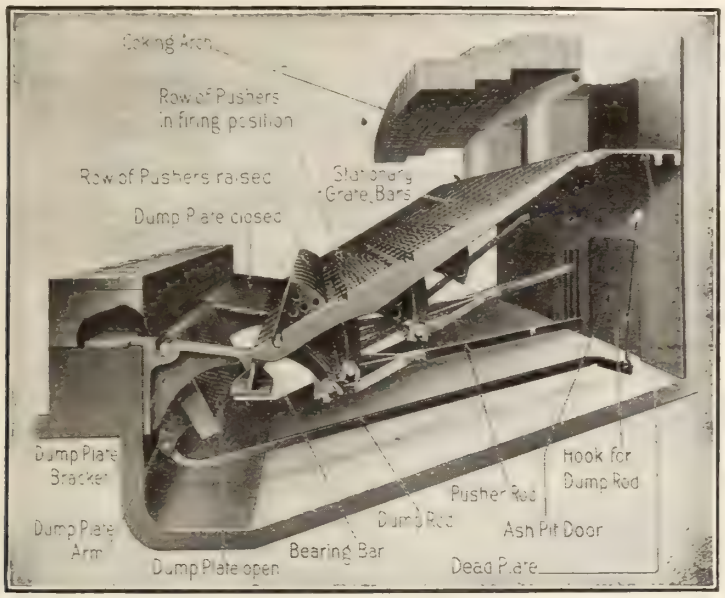


Bailey Meter Company Limited

177 Delorimier Avenue, Montreal, Que.

THE NATIONAL STOKER

Installed under any type of Boiler



With the "coal strike" always with us or being promised you must look to mechanical means to guarantee you the highest possible efficiency in the use of the coal you buy

The highest boiler efficiency and capacity with a given coal and furnace can be realized only when the coal is fired continuously and uniformly and there is no variation in the air supply. With hand firing this requires frequent firing in small amounts, even and skilful distribution over the entire surface of the coal bed, and careful adjustment of the draft. This "close attention" is mighty hard to get. With the National Stoker, high efficiency and capacity are secured with very little effort or skill. Without resorting to the complication and expense of mechanical stokers, the National Hand-Operated Stoker enables relatively unskilled firemen to get economical and smokeless combustion with all kinds of coal, with a minimum of labor. Can easily be installed in your existing plant.

Let us send you full particulars of this economical National Stoker.

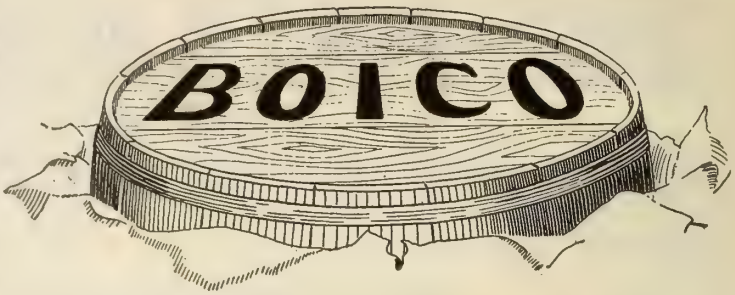
The Safe and Certain Boiler Cleanser

PUT a barrel of BOICO in your boiler room. It's the most efficient and economical **clean-boiler insurance** you can adopt. BOICO routs the most stubborn cases of boiler scale formations quickly and thoroughly.



Hundreds of Plants are Using BOICO Every Day With Unqualified Success

What BOICO will do in one plant it will do in another—**it will do in yours.** BOICO loosens and brings away the hardest of old formations and keeps new scale from gathering. Yet it never does the slightest injury to boilers, valves or packings. Neither does it carry over in the steam, nor cause foaming or priming.

We are confident that BOICO will live up to all our claims and are prepared to let you test it FREE of cost. You have nothing to lose by trying it—let us hear from you.

Anti-Clinker Shell Bar Grates

There's no coal waste where these grates are used. Maximum air-space provides for perfect combustion. No clinker formation here, and you get more heat with less fuel.

One-Piece Jointless Furnace Lining

Why shift the blame on your engineer or fireman when it is your furnaces that are not up to the highest point of efficiency? USE PLIBRICO—it lasts longer than fire brick and is easier to instal.

Tip-It Patent Welding Process

With TIP-IT you get tools with shanks of carbon and tips of high-speed steel.

De Laval Centrifugal Pumps
For Steam and Electric Drive

THE De Laval steam-turbine-driven centrifugal pump is the cheapest means for handling water. The combined unit costs less than a reciprocating pump, occupies less space and is less expensive for repairs and upkeep. There are no valves, plunger packings, or reciprocating parts to be kept in order. Lubrication is automatic, the same oil being used over and over. The overall efficiency, including all operating costs, is much greater than that of a reciprocating unit.

Two De Laval geared steam turbine driven pumps, and two De Laval motor driven pumps in the plant of the Corporation of Brantford, Ont. The turbine-driven units are designed to deliver 2,800 gal. per min. each against 100 ft. head and the motor-driven units to deliver the same quantity each against 200 ft. head. The turbine driven units can be operated in series, when desired.

For electric drive, the De Laval centrifugal pump is ideal, because of its high efficiency and power-limiting characteristic, which protects the motor against overload. The size of the motor can be chosen to give the highest efficiency at the designed load, which reduces first cost, and in the case of induction motors, results in a higher power factor. The low starting torque permits also of the use of synchronous motors for correcting power factor.

State your pumping problem in detail, including kind of power available, and our Engineering Department will advise you fully. Ask for special publication B100.

Sole Manufacturers of the celebrated "MAPLE LEAF" Brand Stitched Cotton Duck Belting and Belt Dressing.

The demand for our products has steadily increased because the standard of quality has been maintained.

We make only one grade, the best that can be produced.

"MAPLE LEAF" is the strongest, truest running, most economical and efficient belt on the market for transmission of power, conveying, etc.

Being thoroughly waterproof it is suitable for running in wet or dry places. **"MAPLE LEAF"** Belt Dressing is different to others offered in that it is equally good for all kinds of belting, leather, rubber, or Balata, as well as our own make.

Write us for prices, and if desired we will be pleased to furnish samples and further information.

A trial order will convince you of their utility.

DOMINION BELTING CO., Ltd., Hamilton, Canada - Quebec Branch: 51 Duluth Bldg., Montreal

Is this hint from a reader Worth anything to you?

A STRIKING message to manufacturers of power-house equipment is derived from a letter written by a "Power House" reader in reply to a request for a criticism of the paper and for suggestions as to how it could be improved. In asking for criticism it was to the editorial portion of the paper rather than to the advertising that reference was intended, and there was no expectation of eliciting such a remarkable testimonial to the paper's efficiency as a medium of publicity. This spontaneous tribute should therefore have a doubly convincing effect. Here is the letter:

Circulation Manager Toronto, April 8, 1922.
Power House.

Yours of April 5, 1922, to hand asking for my candid opinion about Power House. Any opinion other than an honest one is worthless and some parts of the following may not be just to your liking but it is at any rate honest.

I believe Power House compares favorably with other power-house journals in many respects. One department I would like to see at least three times its present size is the selling section. Many of the ads. are from all-American U.S. firms but there must be many others, some of them with Canadian branches and agencies, who do not carry an advertisement in Power House. **This is a mistake on their part,** but for all I know to the contrary it may be due to the lack of energy on the part of the Power House ad. manager in getting after them. **It is an absolute fact that the engineer is more than ever dependent upon his technical journals for information in connection with new ideas in power plant equipment. He does not depend upon the reading pages SO MUCH AS ON THE ADVERTISEMENT PAGES.** I write from experience. For the past twenty years I have been first engineer in different government-owned power-plants and I have, time and again, secured ideas tending towards improved conditions in power-plant work from the selling section of Power House. The buyers' directory is good, I would like to see the advertisers index several more pages....."

Suppose you were asked—

by an engineer to tell him something about your products—you would jump at the chance, of course. Well then, do you realize that twice every month some 4,000 such men—men vitally interested in your products—are literally **asking you** to tell them something about your products. That is why these men subscribe to "Power House" (a Canadian journal devoted entirely to Power Plant Efficiency in Management, Equipment and Operation), because they want to know in just what way **your products** will benefit them. **Why don't you tell them?**

We offer you the experience of our Advertising Service Department for the preparation of your messages; in fact for everything from specific information to the planning of an entire campaign. Make use of us; but, before everything else, properly appreciate the unique value of Power House as a medium and make use of it.

that Asbestos is heat proof, acid resisting, long wearing—therefore he wants packings made of Asbestos. To be doubly sure he specifies

Raybestos PACKINGS

"They Wear Longest"

WHEREVER Packings are used, Asbestos is recognized as the important factor for heat resistance and long wear. Wherever Asbestos is known, the long-fibre, silky Asbestos from the Canadian Thetford Mines, is recognized as possessing exceptional strength and quality.

It is from this that we make the Packings that bear the name "Raybestos."

This name signifies all that is best in Packings—this brand is specified by engineers wherever power is transmitted—wherever gas, steam, and liquids are controlled by pressure or conveyed within unnatural bounds.

Use Raybestos Packings for Pipe Flanges, Cylinder Heads, Piston Rods, Valve Stems, Plungers, Boiler Manhole and Handhole Plates—and all Packings for Air, Steam, Acid, Oil or Ammonia.

They stand for true economy because they wear out slowly.

Dayton-Dowd

Type CS Single Stage Double Suction Centrifugal Pump.

CENTRIFUGAL DD PUMPS

Note Ease of Access to All Working Parts

The single stage C.S. centrifugals are furnished with impellers of the enclosed, double-suction type. The design and finish of the impeller determines in a large measure whether the pump will meet its specified conditions. Years of experience in centrifugal pump designing and comprehensive tests enable the Dayton-Dowd Engineering Department to design the impellers and acquire the maximum efficiency possible for any specified duty.

The C.S. pumps are of the non-overloading type, and so designed that power consumed under any conditions of variation of head will not exceed the power required under normal operation. This feature protects motor from overload.

Bulletin 240 contains valuable information regarding Dayton-Dowd Centrifugal Pumps. Shall we send it to you?

Refrigeration For The Power Plant Engineer

The Single and Double Acting Compressor, Water Jacketing, Wet Compression and Oil Sealing, Oil Separators, Different Types of Condensers, the Liquid Receiver, Are All Described in This Article

By T. H. FENNER

IN the last article of this series, a general diagram of an ammonia compression refrigeration system was given, showing the compressor situated between the expansion and condensation side of the system. In actual systems, of course, the layout is not exactly so symmetrical as this, but the compressor is of course the central part of the system, whether it is situated in the exact physical centre or not.

Taking this as the starting point we shall describe one or two types of ammonia compressor, both of the double acting and single acting design.

In general, the single acting compressor draws ammonia gas into the cylinder on the suction stroke, while on the return stroke the gas passes through a valve situated in the piston of the compressor, as the piston displaces it. On the third stroke this gas above the piston is compressed and discharged, while a fresh charge of gas is being drawn in on the under side of the piston. Thus after the machine is under way, there is a charge of gas drawn in, compressed, and discharged at each revolution.

In the double acting compressor, there is a suction and discharge valve at each end of the cylinder, and each stroke is a suction and discharge stroke, there thus being a charge drawn in, compressed and discharged, at each stroke, or twice every revolution. In the single acting type, there is a suction at one end of the cylinder and discharge at the other while in the double acting there is a suction and discharge at each end of the cylinder.

Compressors may be vertical or horizontal, and may be driven by a steam engine, or a motor, either direct connected or belted. The steam engine is usually direct connected to the compressor, while the motor, owing to its higher speed, is usually connected to the compressor by a belt. In some cases the motors are direct connected to the machine, but this is usually on small sizes.

A CORRECTION

In the article appearing in last issue, on page 21, column 1, under the subhead "Cooling Effect," there is a typographical error. Instead of 29.4 lbs. absolute, the line reads 294.4 lbs. absolute which is obviously ridiculous.

Single Acting Compressor

Figure 1 is an illustration of a single acting vertical water jacketed compressor. The water jacket is made of sheet metal, and is supported by the bottom flange of the cylinder, which is extended for this purpose. It will be noticed that the water jacket is left open at the top, the effect being that the compressor is surrounded by a tank of water. The water simply overflows, the cold supply water sinking to the bottom of the jacket, making a circulation. The valve at the right hand side is the suction valve, while the valve in the piston is plainly shown. The piston itself is packed by four rings, and the valve seat is secured to the piston by setscrews. A light spring is set on the suction valve in the piston, in order to ensure its seating correctly.

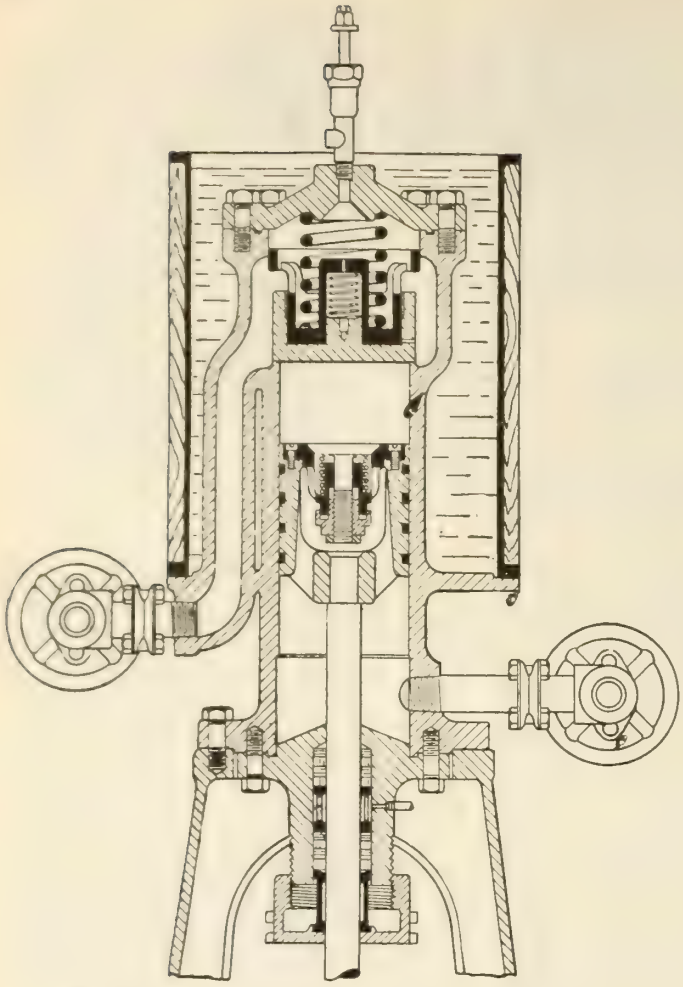
The discharge valve is carried in a casting which sits on top of the cylinder liner, and is held down by a spring. This is known as the safety head and it is so constructed that if anything should get between the top of the piston and this head, the whole thing will be raised against the pressure of the spring thus avoiding any damage to the cylinder cover itself. The discharge port is seen at the left of the compressor, with the discharge valve at the bottom. The piston rod is packed by a special form of stuffing box, known as a lantern, which contains soft packing at each end, and in the centre is an annular bobbin, which leaves a space between the stuffing box and itself, into which oil is pumped under pressure. The small oil connection can be seen in the illustration. Fig. 2 shows another type of single acting compressor, and the construction of the false or safety head is clearly shown in this illustration. The water piping for the jacket is also shown, entering the jacket at the bottom on one side and overflowing at the top on the other side. There is no discharge port in this case, the discharge valve being situated at the top of the compressor cylinder.

In the single acting compressor the stuffing box packing is only exposed to the suction pressure, so that it is not such a difficult matter to keep it packed, the pressure being only from atmospheric to a few pounds above or below. The temperature is therefore fairly constant, and the rod more easily kept cool.

The Double Acting Compressor

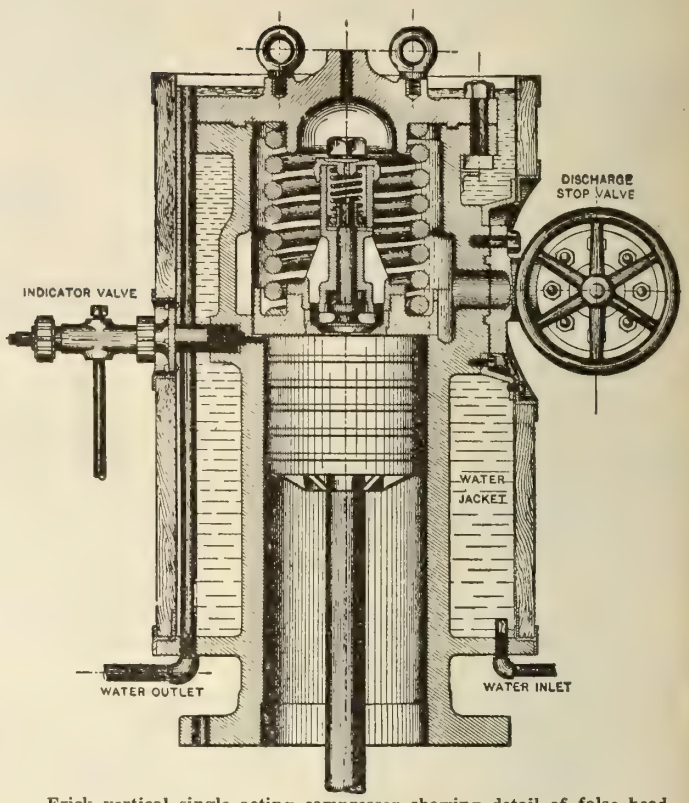
In Fig. 3 is shown a section of a double acting compressor as made by the Linde people. The arrangement of the suction and discharge valves can be seen very clearly, the suction valves being on the bottom and opening inwards, the discharge valves being on the top and opening outwards. The piston is made with hemispherical ends, and the cylinder heads are made to conform to the shape of the piston, so that clearance is kept down to a very small amount. The absence of any water jacket will be noted. This type of compressor works on the wet system, that is, a certain amount of liquid ammonia is injected into the cylinder on each stroke, which is evaporated by the heat of compression, and this absorbs the heat that is otherwise absorbed by the water jacket. The arrangement of the stuffing box and packing are plainly seen.

Figure 4 shows a view of a vertical compressor as made by the De La Vergne people, and this is of the oil sealed type. At the bottom of the cylinder and on top of the piston will be noticed a thin film of oil, and this is used for filling the clearance space at the end of the stroke. This oil also takes up some of the heat of compression, thus fulfilling the same purpose as the water jacket or the liquid ammonia injection. It will be noticed that at the



Single acting York compressor with tank water jacket.

After the gas is compressed, and on its way to the condenser, it passes through an oil separator. An oil separator on a refrigerating machine serves the same purpose that it does on a steam heating plant, which is to intercept oil that would otherwise get through to the system and insulate the coils. If oil gets in the ammonia coils it will cut down their effectiveness very largely, just as it would do if it got in the coils of a heating system, as it is a very poor conductor of heat. The oil separator usually consists of a vertical cylindrical vessel, into which the gas is led from the top, and again taken out at the top. In its passage through the separator it strikes against baffles of various kinds, the result being that any oil which is entrained with the gas, drops down on striking the baffles, and is collected in the bottom of the separator from which it may be drawn off. It is very important that these separators should be carefully looked after, and cleaned out at regular intervals.



Frick vertical single acting compressor showing detail of false head.

bottom of the cylinder there are two discharge valves one above the other. The idea of this is to minimize the clearance space at the bottom of the cylinder. There are ports in the piston which allow the gas to pass through the piston and out of the upper valve when the lower valve is closed by the piston passing over it. It will be noticed that stress has been laid on the avoidance of unnecessary clearance in the compressor cylinders. This is just as necessary with ammonia gas as with steam, for if there are large clearance spaces, it means that a considerable quantity of gas is required to keep them filled, and this gas must be alternately compressed and expanded with each stroke of the machine. Therefore the less clearance space the better.

Fig. 5 shows a Buffalo compressor of the vertical double acting type, provided with a water jacket. Clearance is kept down by having the valves on the sides of the cylinder, thus allowing the piston to come close to the heads at the bottom of the stroke, while on the top of the cylinder the same condition exists. The general arrangement of valves, water jackets, stuffing boxes and oil supply are well illustrated by this cut.

These illustrations show the different general types of ammonia compressors, though there are many makers of machines not among those illustrated. It will be seen that in the design of a compressor the objects sought are minimum of clearance space, adequate means of absorbing the heat of compression, either by water jackets, oil seal, or liquid injection, and accessibility with ample passages in the suction and delivery valves. There is another important point in connection with the suction and delivery valves on compressors, and that is the provision of means to prevent the valves falling into the cylinder in case a stem should break. This has been the cause of several bad accidents in the past, but in most cases at the present time there is a safety arrangement of some kind to prevent this happening.

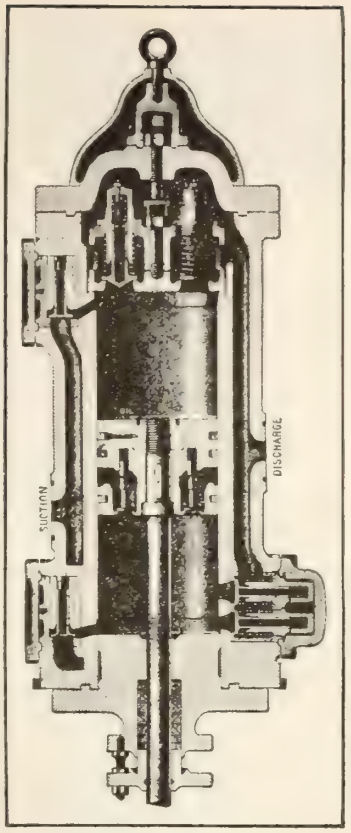
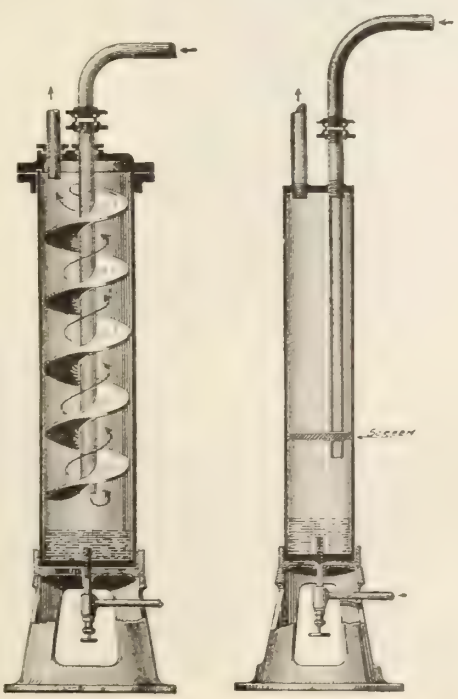
Buffalo Vertical Compressor Water Cooled. The oil well is connected to the suction valve, so that any gas passing into the lantern is drawn into the suction. Note safety collars on valves to prevent them dropping into cylinders.



DeLa Vergne Vertical Compressor with oil seal for filling clearance and double discharge valves on bottom of cylinder.

The Condenser

One of the most important parts of the refrigerating system is the condenser, and there are several types of this apparatus. These are known by names which give a good indication of the differences between them, or rather of the particular characteristics of each. There is the shell condenser, which corresponds in a great degree with the surface condenser known to steam practice, being a shell containing tubes through which circulates the water for cooling or the gas to be cooled as the case may be. In the case of ammonia it is usually the water outside the coils and the ammonia inside, the reason of course being that the ammonia is at a comparatively high pressure, and it is much easier to confine it in the coil than to build a tank strong enough to contain the pressure. The tank may be either round or square, and the coil may be spiral or flat. This type of condenser is usually known as a submerged condenser, and the gas usually enters at the top, the liquid being drained off at the bottom, while the condensing water enters at the bottom, and overflows at the top. This is the best way of effecting a transfer of heat, and is adopted in all cases where such transference has to be made, and is known as the counter current principle. Thus the cold water entering the bottom of the condenser encounters the liquid which has a temperature of perhaps only 10 or 15 degrees higher than the water. As the water travels upwards, it is constantly absorbing heat, and its temperature is being raised. When it reaches the top, it is in contact with the hot gas coming from the compressor, so that, although the temperature of the circulating water has been increased in its passage through the condenser the gas it is in contact with at the end of its journey is still at a considerably higher temperature than the water. This enables a considerable transfer of heat to take place all through the condenser.

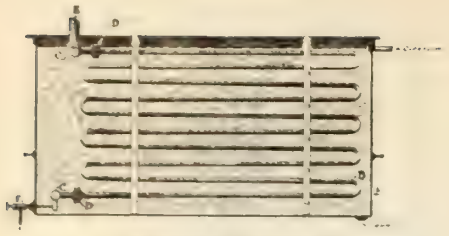


Types of oil separators.

The Atmospheric Condenser

This submerged condenser is a bulky arrangement, and a heavy one, and is not much favored on that account. The atmospheric condenser is probably the most important, and the most generally used of all the types. It is usually situated on the roof of the building, and consists of a series of coils, laid horizontally, and in stands about twelve pipes high. Over the top of each stand is a trough, which is supplied by the cooling water connection, and allows the water to trickle down over the pipes. Owing to the fact that the condenser is exposed to the air, the amount of cooling water required is considerably less than with the submerged type. The circulation of the air among the tubes or coils carries a certain amount of heat away, and the absorption of the water by the air coming into contact with it also requires heat which is furnished by the ammonia in the coils. A certain amount of water is evaporated which also requires heat, which is taken from the coils, so that the latent heat of the water is utilized to a certain extent in absorbing heat, lessening the amount to be dealt with by actual convection.

The gas is introduced at the top in some cases, but this is not so efficient, as the flow of the water and the gas are in the same direction. The gas can be introduced at the bottom of the stand of coils, and pass upwards, drain pipes being provided here and there on the coils



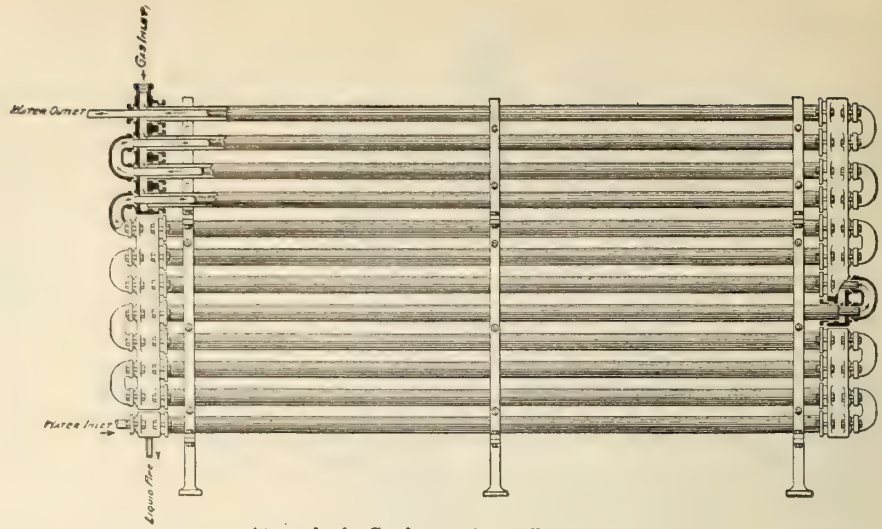
Submerged Condenser.

to collect the liquid as it is condensed, and draw it to the liquid receiver. This is probably the most efficient form as it employs the counter current flow just described. When the gas and water flow in the same direction, we have the hottest gas being in contact with the coldest water. The temperature of the water is therefore increased very rapidly at the beginning of its flow, and as it progresses its temperature is getting nearer the temperature of the gas, lessening the efficiency of the heat transfer. It is of course just the opposite effect to that of the counterflow principle.

The Double Pipe Condenser

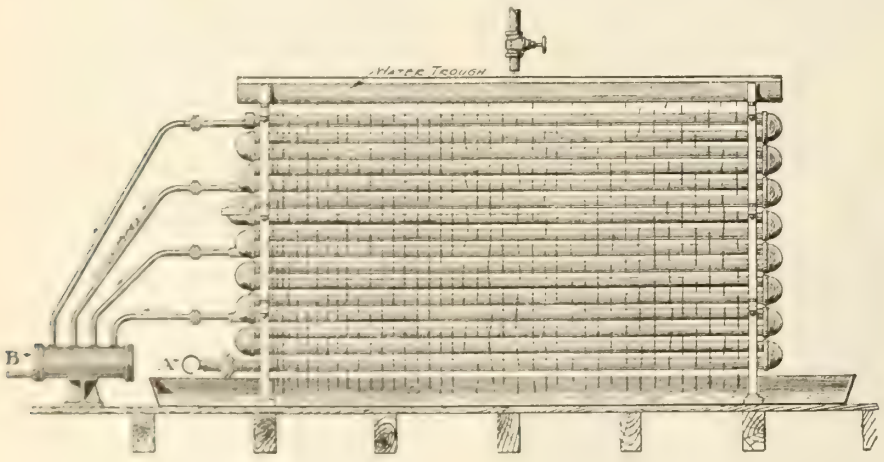
In the double pipe condenser another principle is introduced. In this case one pipe is placed inside another, leaving an annular space between the ou side of one pipe and the inside of the other. The ammonia gas is circulated through the inner pipe, and the water through the outer, or the reverse may be the case, the water being in the inner pipe and the gas in the annular space. The arrangement allows of a very good contact between the gas and the circulating water, as the comparatively small space causes the gas to churn along on its way, thus coming into intimate contact with the pipe walls, and allowing the water to get its most effective work of convection in. The counter current flow can be well utilized in this arrangement, while it is compact and easily accessible for repairs.

The arrangement is easily understood from the illustration, which shows a double pipe condenser the water being in the small pipe and the gas in the annular space surrounding it. The counter current flow is shown.



Atmospheric Condenser Contraflow System.

In the course of opera ion of the system, there is from time to time the unavoidable entrance of foreign matter which is non-condensable such as air which may be drawn into the low pressure side of the system through a leaky joint, and compressed and discharged into the high pressure side. This will affect the efficiency of the machine, and provision has to be made to get rid of such matter. On the top of condenser there is usually a valve or valves, for the purpose of purging or clearing out the foreign gases from the condenser. The method usually adopted is to place a pipe from the valve into a pail of water, and then open the purging valve. As long as there is any gas other than ammonia being discharged, bubbles will rise to the surface of the water in the pail, but as soon as the condenser is clear, and pure ammonia is coming, the bubbles will cease. This is because the water will absorb pure ammonia gas, but will not absorb a mixture of air and ammonia, the air escaping as bubbles. There are thus two places from which objectionable matter can be extracted from the system, one being the oil separator before the condenser is reached, and the next being the purging valve on the top of the condenser.



Atmospheric Condenser.

The Receiver

After the ammonia gas is condensed, it drops down the condenser coils into a tank known as the liquid receiver. This is a tank very similar in construction to the oil separator tank illustrated, and it forms really a reservoir between the condenser and the expansion valve. The liquid enters at the top, and is drawn off at the side of the tank a little distance above the bottom. This allows for any scale or other impurities settling on the bottom of the receiver from whence they can be drawn off, thus avoiding the chance of the expansion valve seats being scored or the valves held off the face through small pieces getting on the seats.

Following the liquid receiver, the next feature we come to is the regulating or expansion valves, and these will be discussed in a later article.

BOOK REVIEW

We have received from the McGraw Hill Book Co., Inc., of New York, a copy of a new publication entitled "Steam Power Plant Auxiliaries and Accessories." The book is edited by Terrell Croft, of the Terrell Croft Engineering Co., himself the author of a number of books on engineering subjects. The present volume is along lines which should appeal very strongly to the power plant engineer. It deals in a very complete manner with the various auxiliaries and accessories to be found in a modern power plant, illustrating each one very fully, and also goes into the economics of the question, showing by calculation just where the advantage or otherwise of certain types of auxiliaries lies.

The first chapter of the book is devoted to pump calculations which are of great interest to every engineer, and these are followed by chapters on direct acting, crank action, and centrifugal pumps, injectors and various feed pump governors, feed water heaters, economisers, separators, steam traps, etc., are all very fully gone into. This is one of the most useful books for the power plant man that we have seen for some time.

The Importance of Emergency Closing Valves

When an Accident Happens to a Steam Turbine Running With High Velocity Steam, the Arrangements for Closing Off the Steam Quickly and Safely Are Very Important—The Method is Described Here

By P. W. KNAUF*

IT HAS for a long time been general practice to install gate valves at the boiler end of steam pipes serving turbine units so that the steam can be cut off when a turbine and its throttle valve are opened up for inspection, cleaning or repair. In order to operate such valves the attendants are obliged to climb to the top of the boilers. For this reason the valves are frequently equipped with motor drive, with control stations in the boiler room and elsewhere.

Motor drive, however, does not convert a large gate valve into an emergency shut-off valve. A gate valve cannot be made to lose instantaneously. In fact, it should only be closed at times when there is no steam flow or opened when the pressures existing on both sides of the gate have been equalized by means of the by-pass customarily provided. Under such balanced conditions, with the usual size motor and gearing, the speed of closing the gate, that is, the rate of travel of the gate spindle is about 1 ft. per min. An 18 or 20 in. valve therefore requires nearly 2 min. to close by electric motor drive.

If for example the attendants are unable to get near the turbine throttle valve, as has happened frequently, or if the throttle valve is for some reason inoperative, when the motor driven gate valve must be depended upon to shut off the steam flow to the turbine, that is, the gate valve must close when the steam flow through it is, depending on the load, anywhere between 5,000 and 13,000 ft. per min.

A far more severe condition is a rupture of the pipe between the header gate valve and the turbine. In such an event the gate valve must be closed instantly in order to prevent the boilers from being blown down. Under these conditions, the gate must be forced perpendicularly through a steam velocity that is many times in excess of full load flow because boiler pressure exists on one side of the gate and an open end or atmosphere on the other.

The effect of closing a gate valve when a high velocity flow is passing through it is that the bottom edges of the gate or discs will be tilted or dragged in the direction of flow as these enter to close the ports. The result is that the gate will be jammed in the body guide-ways, and if not actually stalled, the speed will be greatly retarded and the power required enormously increased. Under the most favorable conditions it is therefore unreasonable to expect the gate to complete the travel from the full open position to the shut position in the same time as under no flow conditions. In case of pipe rupture or turbine trouble time is precious. Instantaneous response to automatic or hand control is vital; to wait two minutes or even one minute under such conditions for a long travel valve to screw itself shut is entirely out of the question, especially when all the conditions are in favor of failure.

An emergency closing valve must under the conditions enumerated close instantaneously but without shock. It must primarily be safe and dependable. The purpose of this article is to describe a new type of cushioned emergency closing trip valve that has recently been developed and installed in some of the large central station, lighting, and electric railway companies.

An emergency closing valve must under the conditions enumerated close instantaneously but without shock. It must primarily be safe and dependable. The purpose of this article is to describe a new type of cushioned emergency closing trip valve that has recently been developed and installed in some of the large central station, lighting, and electric railway companies.

The valve, which is of the balanced combined trip and throttle type, is shown in the open position in Fig. 1, and con-

Fig. 6.—Diaphragm type pressure regulator.

sis.s of an easy flow, excess are a globe body having disc connected to a non-rotating spindle which, in turn, is suitably connected to a rotating spindle having a spindle thread. This thread engages with a nut that is free to slide in the yoke end or arch. Pivoted about a stationary fulcrum on the yoke is a lever, of which the shorter arm is connected to the yoke by means of a spring, and the longer arm is arranged to engage in a hook controlled by the tripping mechanism. This longer arm of the lever is known as the latching up lever and is connected by means of pivots to the sliding nut mentioned above. The engagement of the latching lever with the trip hook is assisted by two tension springs, one on either side of the yoke. The steam inlet is above the valve seat and the outlet is below the seat—the disc therefore closes in the direction of the steam flow (not against the steam flow) and after having seated is held shut by the steam pressure.

Fig. 2 shows the general relation of the principal parts. The tripping mechanism of the valve shown in Figs. 1 and 2 is actuated by a hydraulic cylinder under 25 to 75 lbs. water pressure. The mechanism can, however, be electrica ly operated on 125 or 250 volts direct current.

The operation of the valve is as follows, see Fig. 1: Assume that a pipe rupture occurred on the outletside of the valve, or that the steam pressure has dropped below the minimum allowable boiler operating pressure. This in turn will cause a diminution of hydraulic pressure in the relief type, thereby causing the piston in hydraulic trip cylinder to be moved to the left. Under these conditions, the latching up lever is disengaged and the unbalanced steam pressure acting on the top of the main valve disc and the non-rotating valve spindle closes the valve instantly. The closing is assisted by the coil tension closing spring.

To open the valve, it is first necessary to turn the hand wheel in a clockwise direction, whereupon the sliding nut is moved toward the valve body and the latching up lever re-engaged with the trip hook. Thereupon turning the hand wheel in a counterclockwise direction forces the disk off its seat and opens the valve.

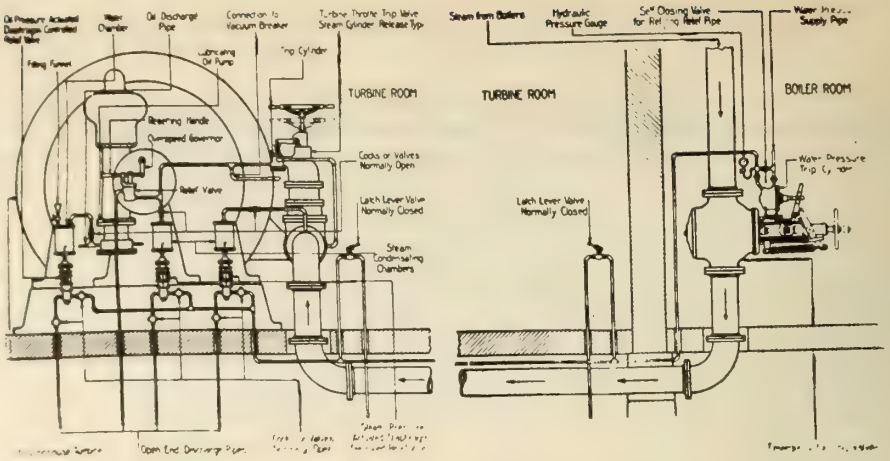

Fig. 3.—Arrangement of Emergency Closing Valve Having Hydraulic Trip Cylinder Release for use on steam mains to large turbine units.

A typical arrangement of the valve having a hydraulic trip cylinder release with four methods of distant control is shown in Fig. 3. The water in the hydraulic trip cylinder and relief pipe is ordinarily under 5 lbs. pressure gauge, and is taken from the city main or from the discharge side of the boiler feed pump. It is introduced into the system through a self-closing valve that is closed as soon as the relief pipe has been filled. There are four methods of distant control divided respectively by a number of latch lever valves in the relief pipe, a diaphragm controlled relief valve operated by steam pressure in the steam pipe serving the turbine, a second such relief valve operated by the overspeed governor, and a third relief valve actuated by the pressure of the lubricating oil.

The latch lever valves are normally closed and are hand operated. Any number of them can be installed. If a latch lever valve is opened, a flow of water occurs in the relief pipe—thereby diminishing the hydraulic pressure to the left of the piston in the trip cylinder, releasing the latching up lever and triping the emergency closing valve.

The diaphragm controlled relief valves are of the type shown in Fig. 4. A diminution in pressure in the chamber above the diaphragm permits the spring to rise and to open the valve, thus permitting a flow of water to occur through the bottom of the valve,

Ordinary cocks are installed on the relief piping on either side of each of the diaphragm controlled relief valves. These cocks are normally open. When the overspeed governor of the turbine is to be tested, when steam pressure is being built up, or oil pressure is being built up, the cock immediately before each diaphragm valve is open, but the other one is closed. These cocks also permit inspection or removal of the diaphragm valves while the turbine is in opertion.

The emergency closing valve is adapted for use with various methods of control in addition to the one described above. Fig. 5 shows an arrangement of the so-called closed circuit direct current type, 125 to 250 volts.

Here an electro-magnet is utilized, the armature of which is a swing weight that, when the circuit through the magnet is broken, drops and trips closing valve shut. Current flows continually through the electro magnet, one or more self-closing push switches, a diaphgram contact breaker (the contacts of whih are normally closed) actuated by the steam pressure, through a second diaphgram contact breaker actuated by the lubricating oil pressure, and finally through a switch on the turbine throttle trip valve. The electro-magnet, push switches, contact breakers, etc., are all connected in series.

The contacts of the switch on the throttle trip valve are normally closed.. They are broken by the tension rod of the overspeed governor when the turbine overspeeds. Under these conditions, not only does the turbine throttle trip valve close, but inasmuch as the switch is opened, the emergency trip valve is also closed.

Here, as in the other arrangement, four methods of distant control are available, of which one or all can be used. Three indicating switches are ordinarily installed for short circuiting the contacts of the diaphragm circuit

(Continued on page 35)

On Coal and Ash Handling Equipment

The Numerous Types of Apparatus for These Purposes Are Described in Outline, and the Suitability of One or the Other is Indicated Under Differing Conditions

By HARRY R. WESTCOTT, of Westcott & Mapes, Inc., New Haven
Read before the Students of Engineering, Yale University

FUEL IS and always has been one of the vital factors behind international politics. The controversy between France and England revolves largely around coal and ore. England is afraid that France is getting too much coal and ore away from Germany. The controversy between Mexico and the United States is largely one concerning fuel, but in this case it is oil.

Fuel, and particularly coal, is a basic commodity which is fundamental to the life of every nation. To-day it stands in the very foreground of our business conditions. Linked with it and equally as important is labor and transportation.

We know that our transportation systems were in 1917 the cause of one of the most perilous coal shortages that we have ever faced. We also know that the present transportation situation has a very unfavorable effect upon the price of coal. What is true now regarding coal, labor and transportation will always be true, so long as there are storms on the sea, cycles of prosperity and adversity, and strife between capital and labor.

It is peculiar that coal, labor and transportation should be so closely related that a disturbance in one, be it economic or otherwise, is accompanied by a like disturbance in the others, the effects of which are so far reaching that it may lead to the expenditure of amounts reaching into the millions for coal handling and coal storage equipment as an economic safeguard, as well as for the purpose of conserving labor and decreasing costs.

The typical coal handling and storage equipment for power station service includes machinery for unloading from barges or cars, crushing, yard storage, reclaiming, conveying to overhead bunker and larry or automatic scales.

The selection of this equipment should be governed by the means of transportation, the amount of coal that is to be unloaded per hour, amount to be stored per hour in yard, total to be stored in yard, hourly reclaiming capacity, bunker capacity, amount to be distributed per hour to boilers, installation cost, cost per ton to handle the coal, flexibility and ability to meet future development.

At this point, I would like to explain that the hourly unloading rate and handling rate as commonly used is incorrect, referring as it does to the average maximum conditions. The correct hourly rate is on the basis of unloading the average maximum shipment in a day's shift or any other given period of time. This, you will observe, includes delay due to moving boats, cars and other causes. This correct hourly rate, which is the effective rate, is frequently 30 per cent less than the maximum rate. On the other hand, the momentary maximum unloading rate should not exceed the capacity of the equipment which takes the coal away.

The proper general arrangement of the system and the correct consolidation of its several units is especially difficult because there is no general agreement as to which type of equipment is best. In other words, the art is not standardized. The various individual units in the coal handling system have made some progress on the road of standardization, but even now in many cases no one can definitely say which particular unit is the best to use under certain conditions.

The individual units have their strong points and their limitations. Mistakes are usually made by trying to use the units to do the things that they are not suited and cannot do efficiently. If less thought were given to the strong points and more to the limitations of the individual units, better coal handling systems would be installed. Instead of that, however, the assumption is usually made that a certain unit will do several things well because it does some one thing particularly well.

In general, the arrangement of the equipment should permit taking coal directly from boat or cars to bunker, without going to yard storage.

In moderate size power houses the storage pile should be alongside of the power house and so intimately and simply linked thereto that the coal in the pile is almost as available as the coal in the overhead bunker. That is, the machinery connecting the coal pile with the overhead bunker should be of the simplest and most dependable type and the distance between the coal pile and the overhead bunker should be a minimum. Where a central coal storage pile of large capacity is required to supply a number of scattered power houses it might not be necessary to install ground storage at the power house. This depends upon the reliability of the transportation medium connecting the central storage and the power houses. Large isolated storage piles for this purpose are not common, therefore, more stress will be laid upon the coal storage for moderate size boiler houses adjacent to the boiler house. The proper type of equipment to employ, however, would not be different no matter where the storage pile is located because the problem of handling coal into and out of the pile is the same.

Yard Storage

It is the opinion of experts that the amount of coal stored at the power station will become greater than heretofore. It is a regrettable fact, but none the less true, that the average consumer is an "11th hour" buyer. The seasonal demand on the coal mines, the transportation systems and the coal dealers, results in all operating under pressure during the seasons of the year when transportation facilities are the poorest; and on the part time during the other seasons when transportation facilities are the best. This is wasteful and is the cause of unemployment, idle freight cars, delays of much consequence and general dissatisfaction. The present modest reduction in the price of coal during the summer months has not been sufficient to cause a greater amount of coal to be stored. Coal provides nearly 25 per cent. of the total tonnage of all American railroads. If the railroads could be induced to allow a low season differential rate, which would be sufficient to cause a greater movement of coal during the off season months, the consumer, dealer, railroad operator and miner would profit. The storage of coal is also encouraged by transportation difficulties, the strike menace, and the desire to prevent excessive prices. The drawback is the cost and the possibility of fires. Notwtihstanding these, however, the storage of coal is on the increase.

Fires are due to coal dust, varieties and sizes of coal store, ventilation and height of pile. It is difficult to control all these conditions except the height and method of piling. Therefore, where space and cost are not too great, the general procedure is to pile the coal not over 20 feet deep, install equipment which can effectively combat the fire and then exercise eternal vigilance. On that basis, fires can be controlled if taken at the beginning. I would point out, however, that coal is frequently piled more than 20 feet deep, especially when very large quantities are stored.

Delays in delivery are usually due to transportation and labor difficulties. The amount of coal to be stored outside depends upon the duration of these difficulties. In any event, sufficient coal should be stored in the yard to permit operating the plant during the cessation of delivery of average duration.

Nothing is more uncertain than the

sea and the weather. Fogs and storms may cause a week's delay, and occasionally a barge is lost. Delays in railroad transportation have proved in recent years to be of longer duration.

It is believed, however, that labor troubles are apt to cause the most serious delay. Strikes, particularly at the mines, are liable to last a number of weeks. It is, therefore, becoming common practice to store sufficient coal to operate at least 90 days. Whether this is too much, or too little, depends more or less on where we are in the general business cycle and the supply and demand for labor.

Receiving Hopper

In the past few years, it has been difficult for the purchaser of coal to control the kind of car in which his coal is shipped. However, coal unloaded from cars in the eastern part of the United States is, in the majority of cases from hopper bottom cars and to a truck or receiving hopper. A bucket may be used for unloading, but it will handle only 90 per cent of the coal in the car without trimming and the bucket and car are frequently damaged.

The hopper should be large. Its size should be determined by the largest coal car in use on the connecting railroad or the largest bucket likely to be used. If cars are used, the hopper should be somewhat longer than the overall lengths of the car pens so as to make spotting of the cars easy. The volume of the hopper should be sufficient to hold the coal as it flows from the car or bucket, with the coal handling equipment running. It takes at least fifteen minutes to get fifty tons of coal out of a hopper bottom car under average good conditions, including placing the car and removing it. This is at the rate of 200 tons per hour maximum in a single track hopper. Unfavorable conditions, such as long hauls, wet coal, frozen coal, inconvenient type of bottom dump car, may reduce this to 100 tons per hour. The hopper should be of sufficient size to receive all that drops out by gravity when the car doors are opened. This never exceeds one half of the carload, or 25 tons.

The track at the hopper should be on a slight grade to facilitate moving empties by gravity, or a winch will have to be used.

The hopper may be either wood, concrete, or steel plate, but preferably the last and ¼ in. thick, or thicker. The lower 3 in. should be renewable to provide for the rapid wear. Its sides should have a minimum valley slope of 45 degrees and there should be ample room below it for installing reciprocating feeder crusher, and conveyor drive, all of which should be well protected from the weather. This equipment, where possible, should be above the ground where it will be well lighted and accessible so that it can be sure of receiving proper care. Placing this equipment above ground may necessitate the use of a conveyor from the feeder to the crusher. When unloading by buckets it is customary to provide a screen or bar grizzly over the hopper, to exclude the very large lumps. It is inadvisable to use a screen when coal is unloaded from hopper bottom cars because of the obstruction to continuous flow.

Traveling Bridges

Yard storage can be taken care of by a traveling bridge, belt conveyors, cable cars, a cable drag scraper or locomotive cranes.

It is obvious that all possible arrangements of unloading, storing and reclaiming bridges cannot be discussed in a single paper. Their design depends entirely upon local conditions, coal to be handled, arrangement of property, etc. Two bridges are seldom alike. There are, however, a few principles which apply to all.

(a) The horizontal transportation of coal by a bucket is slow and expensive.

(b) A belt conveyor has greater capacity, is light in weight and requires less power per unit delivered.

(c) A bucket is the only assured means for combating a fire.

(d) The operator should have an unobstructed view of all operations.

(e) The equipment should be able to operate regardless of weather conditions and frozen coal, though frozen coal is not important in some sections of the country.

A traveling bridge can be arranged with a cantilever boom for unloading boats. If this boom extends over the harbor line, it must be hinged to swing back when not in use. Coal can be distributed to the yard by the unloading bucket or by means of a distributing belt and tripper. It can be reclaimed by the same bucket. A cable car system may be used instead of the belt system. If several different kinds of coal are used in a steel mill or gas works, the bridge may also be equipped with a reclaiming bucket and belt. This permits putting coal into storage and reclaiming from storage simultaneously. Obviously, this equipment has a very high capacity, perhaps around 400 tons per hour. It is open to the objection, however, of being unable to simultaneously store in one end of the yard and reclaim from the other.

Another device used for unloading from boats and storing is the rotating stiff leg derrick of a super-type. This is an all steel structure, having a horizontal boom about 100 feet long and about 50 feet above the ground. It uses a bucket which hoists and travels horizontally on the boom, meanwhile the entire structure rotates. It will handle 150 tons per hour and store approximately 10,000 tons.

The cable drag conveyor system may receive coal by rail which is discharged to a hopper and then a pile is built up nearby by a bucket elevator. If coal is received by boat, the pile may be built up by the unloading equipment without the use of a bucket elevator. The coal is distributed by a bucket dragged by a cableway. One end of this cableway is fixed at the bucket elevator, but the other end can be moved from post to post around the periphery of the storage space.

The coal is reclaimed by dragging it back to another hopper at the foot of the bucket elevator. This elevator then raises the coal to a conveyor which takes it to the boiler room. It is obvious that reclaiming is just as efficient and economical as "stocking out."

The first cost of such a system is comparatively low and the "overhead" chargeable to operation is also low.

This system has the advantage of storing coal at a uniform depth over an area of any shape. It does not separate the lumps from the fines, thereby decreasing the likelihood of spontaneous combustion.

It stores at the rate of 100 tons per hour and is suitable for large as well as small capacities where the storage is purely reserve and not active. Sleet and frozen coal are against it and it handles fires with only partial success.

The cable railway is a "half" system which, with one exception, is most effective for large capacities or long hauls. It operates successfully on horizontal or incline runs and around horizontal curves.

The system may be either the continuous loop or shuttle type. The shuttle type operates with two or more cars with parallel tracks or a single track with switch.

The cable may run continuously or intermittently and the cars may be permanently or temporarily attached to the cable. The dumping of the cars is entirely automatic.

This is an especially convenient system for weighing coal, which should be done, however, at the loading point.

The cars are of wood, "V" type mounted on two swivel trucks, four wheels each. The cars are side discharge and are opened by a tripper at any desired point. They may be of 2 or 3 tons capacity. Recent installations have cars of 4 tons capacity with automatic grips, automatically changing from the incoming to outgoing cable while the car is in motion and without an attendant. The car doors are likewise closed by an automatic device before reaching the loading point.

This system runs at a speed of from 200-300 feet per minute, with a range in capacity up to 1,200 tons per hour with one attendant. It is simple and rugged and has very low maintenance charges. It has, however, no ability to reclaim, which is a serious drawback. It is, therefore, more suitable for conveying than for reclaiming. It has the advantage of having its supporting structure buried in the coal. This interferes with reclaiming and may be destroyed by fire.

Automatic Railway

The automatic railway is in many cases the most economical, both from the standpoint of initial cost, operating and upkeep for transferring coal from a receiving point to a storage pile. The

cars are from one to two tons capacity and operate by gravity along a trackway which has declivity of 3 or 4 per cent. The car discharges automatically at a pre-determined point. Upon reaching this point, the car picks up a counterweight which brings the car to a gradual stop. The car is returned up the incline by the force of gravity of the counterweight, which has been raised by the momentum of the car. This system will handle up to 200 tons per hour. The maximum length of the runway is 500 feet. Most of the objections applying to the cable railway and the telepher apply to this system, except as just stated.

The locomotive crane is used for medium-sized systems. It can be combined with a bell system having tripper and short distribution belts, to good advantage. If a crane is used for unloading from boats, it should have an elevated operating cab so the operator can see into the boat. There should be ample room for the fireman. Short booms are preferable because easier to handle and more stable on the track. Such a crane has a continuous capacity of about 50 tons per hour under good conditions.

The telepher or monorail is not seriously considered because of its unavoidable and fundamental defects. It handles only in a single line and therefore has a low handling and storage capacity, considering its initial cost. It reclaims only about 50 per cent. of the pile without hand trimming. Storing from a fixed point is more apt to cause combustion because the lumps are at the bottom and outside, thereby admitting air. Meanwhile, the fines being above, prevent the escape of heat. A good system will cause no great separation of the sizes.

Before leaving the subject of yard storage, I would like to point out that there are many good systems for storing coal in the yard. Reclaiming is more difficult. Fires have to be combated and the only successful means is a bucket. Buckets cannot reach coal under trestles and other elevated structures without excessive and costly hand trimming. This tends to eliminate several of the systems just described and narrows the field down to a system which can efficiently use a bucket for reclaiming as well as storing.

Feeders

A reciprocating feeder should be used for feeding coal from the receiving hopper evenly and continuously to the crusher. This is particularly necessary if run-of-mine coal is received. The feeder should be driven from the crusher to insure simultaneous starting. A better arrangement is to start the crusher first and when it is up to speed, start the feeder by means of special electrical interconnections arranged so the feeder must be stopped first.

If unlimited headroom under the track makes it necessary to elevate the coal between the hopper and the crusher, a belt conveyor or apron feeder should be used in place of the reciprocating feeder. The belt conveyor is generally considered to be dependable and a magnetic pulley may be used with it for removing stray iron. On the other hand, it must be used with caution where large lumps are handled. The reciprocating feeder consists of overlapping steel slats riveted to two strands of steel roller chain which travels slowly on a track.

Crushers

If a large amount of coal is handled, the fines may be by-passed around the crusher thus preventing further breakage and dusting of the fines.

The crusher should be of the two-roll type. The rolls should be of a large diameter (at least 30 in.) to "bite" large lumps of coal. The crusher should be motor driven by means of a belt which will slip off in case large foreign substances enter the crusher. In addition to that, one of the rolls should be provided with relieving springs to prevent breaking the crusher. It should be adjustable if different sizes of crushed coal are required. A flywheel should be provided to even out the power demands. Recently, crushers have been installed in duplicate on sliding bases so that if one crusher breaks down, another can be put into its place. Where there is ample handling capacity and a good reserve of crushed coal, we can see no reason for this.

Belt Conveyors

Where possible, belt conveyors should be used. They are economical of power, dependable, reasonable in first cost and low in maintenance. The speed of a conveying belt depends largely upon the character of the materials handled. As the size of the lump increases, the speed should decrease. The principal difficulty is in feeding the material to the belt so the material will hit the belt the same speed as the belt is moving and the stay on the belt. In other words, keep the belt full. For ordinary crushed coal, belt capacity should be based on a speed per minute for horizontal belts, of not over 250 feet for 12 in. and 400 feet for 42 in. and 20 per cent. less for incline belts. These are conservative speeds which some might take exception to, but it is the writer's opinion that this is a point where conservatism is warranted.

If inclined belts are used, the maximum declivity should not be over 18 degrees because wet or frosty coal will slide on a greater slope. Where space permits, inclined belts are better for elevating coal than bucket elevators, providing the incline belt efficiently fits into the general arrangement of the system. If it does not, the skip hoist is the preferable means for elevating. In other words, the belt conveyor is first a conveyor and only rarely an efficient elevator. All inclined conveyors and bucket elevators also should be equipped with anti-reversing device.

Belts should be of ample width to prevent spilling and if coal containing large lumps is handled, wider belts should be used. A narrow belt to trough properly, must have less plies than a wide one and yet there must be sufficient plies to provide the requisite strength. On the other hand, a wide belt must have plies enough to sustain the load between idlers without buckling, but not so many plies as to trough poorly, even when empty. A short belt carrying the same hourly tonnage will require less plies than a longer one. In any event, it is well to err on the side of too much strength and using rubber at least ⅛ in. thick on carrying side.

Troughing idlers should be not over 4 ft. apart and nearer at loading point, but never directly under the loading point. Return idlers should be about 10 ft. apart. The wider the belt, the nearer the idlers should be. Ball or roller bearing idlers should be used only where power is expensive and then on the basis that the cost of the power saved warrants the extra cost of the ball bearing idlers.

Drives should be at the delivery end of conveyors where possible, particularly on incline conveyors, and tandem drives should be used for heavy loads, especially on incline conveyors.

Adjustable takeups should be used at receiving ends of short belts for tightening same. There should be a weighted idler or gravity takeup, which provides automatic adjustment on long belts.

There should be a continuous decking between the upper and lower sides of belt to prevent coal from falling from the upper side to the lower, or return side and then running between the belt and its pulleys.

There should be a revolving brush at delivery end of all belt conveyors to prevent coal from getting between belt and return idlers. Pulleys should be large, at least five times the number of plies in the belt, so as to eliminate excessive bending of belts and in occasional cases, it is necessary to provide rubber covering to get the necessary friction between belt and pulley.

The drive should be through reduction gears running in oil in a compact, cast iron housing. This should be mounted on a common cast iron base with the motor with flexible couplings on both sides of the reduction gear.

Bucket and Chain Elevators and Conveyors

Bucket and chain elevators and conveyors are of the following five general types, which are arranged in accordance with their merits:

(a) Flight conveyors, which consist of flights at intervals on a single or double strand of chain, with or without rollers. They drag or scrape the coal in a trough and in a horizontal direction only. They will operate on inclines up to 45 degrees at decreased capacities. They are not suitable for handling ashes. Generally speaking, they should be used only in installations where the coal travels 200 ft. or less, or for capacities of 100 tons per hour or less, or temporary systems, though they are widely used in the anthracite collieries.

They are low in first cost, but consume considerable power.

(b) The centrifugal type which elevates only, consists of buckets at intervals on a single or double strand of chain. The buckets fill by digging into the coal in the bottom boot. This is trying work. The discharge at the top is by centrifugal action. It is, therefore, evident that the equipment must run at a considerable speed to dump clear of the top of the elevator. The same type of elevator may have the buckets fastened on a rubber or canvas belt instead of chains. It proves to be a satisfactory arrangement for light, non-abrasive materials having small lumps such as finely crushed coal. Frequently, idlers are placed just below the pulleys at the discharge end for the purpose of completely inverting the buckets when discharging. This is called the "Positive Discharge."

This equipment has an economical capacity of about 35 tons per hour. Its chain speed depends upon the size of the discharge sprocket, as its discharge depends upon centrifugal force. With an 18 in. sprocket the chain speed should be about 175 ft. per min.; 36 in. sprocket, 300 ft. per min.

(c) The "V" bucket, which carries coal when elevating and scrapes it along in a trough when transporting it horizontally. This has V shaped buckets rigidly attached to one or two strands of roller chain. It is obvious that this type of conveyor will not handle anything as abrasive as ashes.

This type has an economical capacity of about 80 tons per hour, and a maximum speed of 100 ft. per min. This conveyor is less expensive to install than the pivoted bucket type, but costs more to operate.

(d) The continuous bucket type which consists of buckets secured usually between two strands of roller chain, or on a belt. The lower edge of each bucket overlaps the upper edge of the bucket below. This arrangement requires the buckets to be filled from a loading chute thereby relieving the equipment from the strain of digging into the coal in a bottom boot. This arrangement also causes the buckets to dump cleanly at a lower speed.

The continuous bucket type is used only for elevating and on nearly vertical inclines.

As the strains of loading are relieved, the carrying capacity is greater and the permissible speed lower, the wear and tear is reduced and the outfit has a longer life than the types previously described when handling equal tonnage.

The maximum speed is not over 150 ft. per minute and it has an economical capacity up to 75 tons per hour.

At this low speed it is evident that the breakage of the coal will be slight. On the other hand, it is sometimes difficult to get a continuous bucket elevator to dump cleanly if the coal is wet, which is often the case. It is suitable for uncrushed coal.

(e) For important work, when the belt conveyor cannot be used, the pivoted bucket machine, which both elevates and conveys through any path, without transferring the coal from one conveyor to another, should be used. This equipment has a capacity up to 200 tons per hour at a speed not exceeding 60 ft. per minute. This is the double strand type with long pitch malleable iron or steel links, having two bars per link. All rotating points are bushed and the chain carried on rolls. The buckets should be either open-hearth steel or malleable iron and designed so the buckets can be easily removed from the chains. The buckets overlap at edge when the chain is in a horizontal position. Malleable iron buckets are better than steel because they better resist the corrosive action of wet coal and ashes. The equipment should include a filler which will not overload or spill the coal or steel shirt boards may be used, stationary and revolving curves or corners, movable dumper or tripper adjustable takeup at lower end and driver. This system was at one time installed quite considerably for handling ashes. Its field is, however, now being restricted to coal.

While this is the most expensive conveyor to install, it is the least expensive to operate, as it takes less power and has the lowest maintenance charges.

All elevators should be encased with steel plate, be self-supporting and bolted together with provision for inspecting and making repairs.

All outdoor belts and bucket conveyors should be enclosed to protect them against snow, sleet and rain.

The wearing surfaces in chutes and hoppers should be at least ¼ in. thick and easily renewable. All chutes should be 45 deg. or more. All rivet heads in contact with coal should be countersunk.

Sharp angles should be avoided and a streamline effect obtained where practical. All gears and belts should have guards. Towers, trestles and other supports should be steel, not wood, and very rigid. Ample space and provision should be made for cleaning, repairing and inspecting the entire equipment.

If designers of coal handling equipment would give more careful thought to these particular matters, which are really very simple ones, there would be far less trouble with coal handling equipment.

The speeds and capacities of conveyors, previously mentioned, are moderate. It is probable that they can be increased 10 or 15 per cent. on very large sizes or on all sizes where the equipment will run but a few hours per day, or where the equipment will receive care and supervision of a high order. Generally speaking, however, for ordinary and average conditions, it is well to be conservative in this particular.

At this point, I would like to again point out that this paper deals principally with coal handling equipment for power stations in the eastern part of the United States. Equipment for special purposes, such as mining, locomotive coaling stations, anthracite handling, and many other varied purposes, may be different, as may equipment used in more distant parts of the world where customs and coals are different.

Skip Hoists

Skip hoists may be used for elevating coal or ashes, and they are exceptionally reliable. Skips are not widely used, however, for elevating coal except in mines, because the skip is intermittent in its operation while the delivery of coal to it is likely to be continuous. If a skip is used, it should in most cases be provided with an automatic loader which takes the coal from the track hopper and fills the skip bucket without overloading, underloading or spilling.

Skip hoists are especially applicable to high lifts, which is where bucket elevators are least desirable.

The skip hoist may be either balanced, counter-weighted or non-counter-weighted. The purpose of balancing and counter-weighting is to save power. It is, therefore, evident that balancing and counterweighting should not be resorted to for small capacities and where power is cheap.

The balanced skip consists of two buckets interconnected so that one bucket goes up as the other comes down. While these are less expensive because of non-duplication of parts, they are a somewhat inflexible arrangement and should not be used unless one is sure that the cycle fits the operating conditions.

Skips may be also of the differential drum type which is an arrangement whereby a drum of varying diameter runs continuously and at a constant speed throughout a complete cycle of loading, elevating, dumping and lowering. While this simplifies the control, it usually results in a more expensive skip.

Skips may be used with either vertical or incline track or a combination of both, depending upon the requirements.

Counterweights are frequently omitted with skips having inclined tracks because of the complications involved. If counterweights are used, their track is frequently vertical, while the skip track is inclined.

Except in very special cases, the maximum hoisting speed should be about 250 in. per minute, where the distance hoisted is 100 in. or more, and the hoist distance must not exceed 150 in. per minute if an automatic loader is used because of the shock to the loader, unless a control is used which slows down the speed at both the top and bottom of the hoist.

Whether or not the hoist should have automatic control is debatable. We feel that it should not in the average plant. We believe ascent should be accomplished by hand operation of drum type controller and descent the same way. Perhaps in very large plants, having competent mechanics available, automatic control will prove satisfac-

tory. Travel should be limited by limit switch on hoisting machine and another at the end of the bucket travel. Controller should be located at loading point. An emergency push button for stopping the bucket travel should be located at the hoisting machine and at the point of discharge. This push button should be of such type that the hoist cannot be started except by the controller.

As the motor starts under full load, it should have a high starting torque, usually around 300 per cent.

Skip hoists should be located inside of building whenever possible. No employee should be asked to do part of his work inside the boiler room and part outside, because of the extreme temperature range in the winter. The hoistway should be totally enclosed because of dirt and decreased liability of human injury.

Workmanship and materials, especially of the hoisting machine, should be of fine quality. Gears should be totally enclosed and run in oil. All bearings should be bronzed bushed.

Outdoor skip hoists are likely to be a source of trouble because the pits fill with water and freeze, causing motors to burn out. This objection can be minimized, though not eliminated, by extending the walls of the pit above the ground. Sleet, snow and ice cause trouble on guides and sheaves.

As little equipment as possible should be placed above bunkers, limiting it to sheaves and bearings because if it is not easily accessible, it will receive little care and no supervision.

Before leaving the subject of skip hoists. I would like to point out that a cable is more reliable than a chain and that none of the moving parts of a skip hoist are in direct contact with the materials handled.

Weightometer

Except for checking weigh larry or automatic boiler scale records, the value of weighing incoming coal is questionable. All coal is weighed as loaded on boat or cars on government tested scales and under government supervision. This weighing is a reliable function. Practically the only chance for error is in coal lost or stolen in transit. Short weights, if found, are difficult to obtain redress for.

Weightometers may be used on either horizontal or inclined belts, but they must be kept away from trippers which lift the belt and from chutes which may affect them by impact.

Tripper

A tripper will be required with the belt conveyor over bunker to discharge the coal to the bunker unless a shuttle belt is used.

On small installations, the tripper may be hand-propelled but in most cases, the tripper should be self-propelled, automatic and reversing taking its power from the belt. It should be arranged so it will travel back and forth between two selected points or so the propelling device can be disengaged and the tripper discharge in one place only. It should be provided with an automatic brush for cleaning the carrying side of belt before passing over return pulley and idlers.

Bunker Gates

These should be cast iron, duplex type operated by an extension shaft, levers and galvanized chains running over pulleys. If the chains extend within reach of the floor, or if a larry is used, means should be adopted for preventing the chains from hanging in the center of the firing aisle and interfering with larry chutes. Gates 16 in. square or larger shoulder lever operated on both sides.

In selecting the size of the gate, consideration should be given to depth of coal over gate, impact on larry due to falling coal, and particularly to the time required to fill the larry, and the size of the coal.

If larries are used, the gates should be interlocked, either mechanically or electrically, so that a gate cannot be opened except a larry is directly below it and then it should be impossible to move the larry until the gate is closed.

Larries Versus Individual Automatic Scales

The larry permits taking coal from any part of the bunker and delivering to any stoker. The larry permits closer spacing of the gate in the bunker and eliminates dead coal which causes fires. The larry also distributes coal properly to the stoker hopper. Lumps, frozen coal and wet coal clog up the chutes and adhere to hoppers of automatic scales. Automatic scales prevent reaching similar coal which sometimes refuses to flow from the bunker. The automatic scales with overhead mechanism, supports, etc., make the firing aisle dark. The scale chutes have to be removed when cleaining boilers.

While the automatic scale is surprisingly free from trouble, it is only so by constant care. In a large plant where many scales would be used, it is probable that as much of an operator's time would be required to care for the scales as would be required to run a larry. As regards records, it is questionable if this refinement at each boiler is warranted when there are other more convenient methods of getting sufficient records of the day's output. I refer to boiler feed or steam flow meters.

Considering first cost, care and maintenance of many small parts, electrical connections, shafting, supports, etc., and the points previously mentioned, preference seems to be for the larry.

Larry

The hand-operated larry is inadvisable in all but the smallest plants.

The larry should be hand-operated, however, as well as electrically operated to provide for failure of current. A braking mechanism should be included. The larry should hold at least as much coal as the stoker hopper with its extension and as much more as possible. The tendency is to make motor-operated larries larger than heretofore.

The larry should, in all but the very largest sizes, have a circular or elliptical hopper with conical bottom and round, easy flow chute. The chute should never be more than 30 degrees from a vertical and its diameter increase ⅛ per foot in the direction of flow. The top of hopper should be designed to check the flow of coal or spilling in case a bunker gate refuses to close. With small size larries, the operator walks, but if the capacity is three tons or more, it is better to have the operator ride with the larry in an elevated cab so as to permit him to see inside of the extension stoker hoppers when filling them. The operator should not, however, ride so close to the bunker as to be in a hot atmosphere.

It should have a beam type device for registering the weight of each load on a card. The scales, but not the hopper, should have 25-50 per cent. overload capacity. It should dump clean so as to prevent weighing any of the coal twice.

Starting and stopping imposes a severe shock on the larry, particularly the knife edges. With a bunker continuously along the front of the boilers, the larry should run at a slow speed and never more than 75 ft. per minute, with provisions for a slower speed when filling the stoker hoppers. The controller should be of the reversing drum type with dead man's stop so the larry stops whenever the operator's hand is removed from the controller handle. A light should be provided at the scale beam.

Automatic Scales

Automatic scales should be totally enclosed in glass to protect them from dust. An overhead walk should be provided for reaching the scales, shafting, motor drives, etc. Each scale may be individually driven by motor or one motor may drive a line shaft through a silent chain with a small chain drive to each scale. The last is generally preferable because of cost. With this arrangement, the shaft runs constantly and there is a clutch at each scale. The chute should have a universal joint at top and removable supports near the bottom so the chute may be swung into the aisle in case of a fire in the bunker or in case it is desired to clean the boiler tubes.

If a spreader is used at bottom of chute at stoker hopper, there should be an open space about 3 in. wide along the front of hopper to permit breaking up arches in the hopper.

Handling Ashes

Ashes are gritty and may be hot or wet. They cause excessive wear and disintergration. Hot ashes may cause fires in the bunker. Red hot ashes cause distortion of handling equipment. Large and extremely hard clinkers are produced by stokers. Ashes are much more difficult to handle than coal because of the reasons just mentioned.

Ash Hoppers and Gates

It is the common practice particularly where stokers are used, to use large bottom opening hoppers beneath the

(Continued on Page 42)

Isothermal and Adiabatic Expansion

An Explanation for the Power Plant Engineer, of These Terms, in Simple Language, and With as Much Elimination of Mathematics as is Possible in This Subject

By T. H. FENNER

THERE are two words which frequently occur in discussions on gases under pressure, and which are closely related to the behaviour of steam in a cylinder, which the average engineer is inclined to be shy of. These are the two words mentioned in the title of this article, "adiabatic" and "isothermal," and they have a very formidable sound, but like most things, are not so bad when looked at closely enough.

It is our purpose in this article to explain the meaning of these terms without getting into any deep mathematical expressions, although it will be impossible to avoid mathematics altogether.

Isothermal Expansion

The prefix "iso" indicates equality or sameness, and the word "thermal" means pertaining to heat. The two joined together therefore express an equality or sameness of heat or temperature. Therefore the word is used to indicate the expansion or compression of a gas under the conditions of uniform temperature.

This is again the law of Boyle, which states that under constant temperature the product of the pressure multiplied by the volume of a gas is constant. This may be expressed by the statement that "providing the temperature is kept constant, the pressure of a gas varies inversely as its volume."

It is from this law that we construct the theoretical curve of expansion known as the isothermal curve, or the hyperbolic curve and this curve shows diagrammatically the variations of pressure and volume of a gas expanding or being compressed from a volume 1 and pressure 1 to a volume 2 and pressure 2 at constant temperature. We can express this law in a single formula, such as

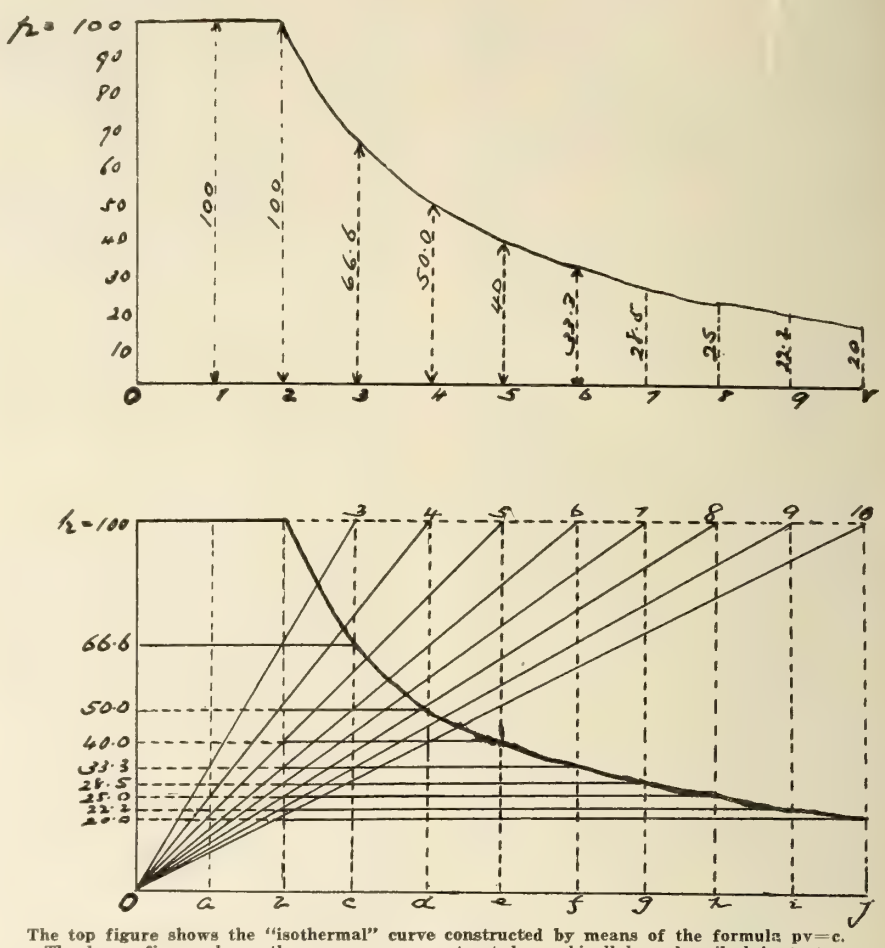
$$pv = p1v1 = p2v2 = c$$

which means that the pressure multiplied by the volume will always give the same result, that is will be a constant.

For example in the illustration we have a pressure represented by 100, and a volume at cut off equal to 2 parts, the final volume being 10 parts. The product of pressure and volume at cut off is 100 x 2 = 200.

At the end of the expansion the pressure is 20, and the volume is 10; 20 x 10 = 200. At any intermediate point we can find the pressure if we know the constant and the volume, or we can find the volume if we know the pressure and the constant.

If p v = 200 when p is 100 and v is 2, then when v is 3 and constant is 200 p will be equal to 200 / 3, or if p is 50 and constant 200, the v will be 200 / 50.



The top figure shows the "isothermal" curve constructed by means of the formula pv=c. The lower figure shows the same curve constructed graphicallyl as described in text.

Thus we have for the total expansion from 2 volumes to 10 the following pressures:

P.	V.	C.
100	x 2 =	200
66.66	x 3 =	200
50	x 4 =	200
40	x 5 =	200
33.33	x 6 =	200
28.57	x 7 =	200
25	x 8 =	200
22.22	x 9 =	200
20	x 10 =	200

We can construct the curve from these calculated values, if we take pressure as ordinates, the volume as abscissae in the diagram. Thus if we lay off a line to represent volume, and divide it into 10 equal parts, and at right angles to it a line to represent pressure, measured from zero, not atmosphere, we have the starting points of our curve. Supposing the steam to be admitted till it occupies two volumes or two of the divisions on the volume line, the pressure will remain at 100, and the line will be a straight one. From this point the steam or gas is allowed to expand, and in doing so it will follow the law that as its volume increases its pressure will decrease, and these changes will be in exact proportion. If we take the pressure at the different points that we have calculated, and erect ordinates to represent these pressures, then a line drawn from the commencement of expansion through all these points will describe a curve. The closer together the points are taken the easier it will be to draw the curve, and there is no limit to the number of points that may be used, except the ability to get the line close together.

We may construct this curve in another manner, preferably by the use of squared paper, but by means of a drawing board and set square in any case. Again take the volume as abscissae and the pressure as ordinates and complete the parallelogram. From the divisional points on the base line erect perpendiculars to reach the top line. Then from the point of origin, that is the cutting of pressure and volume lines at O pressure

and volume, draw diagonals joining the division points on the top line with O.

Now from where the diagonal joining line 3 crosses the perpendicular line 2, draw a horizontal line to line 3. This is the last point on curve. From the crossing of line 4 on line 2, draw a horizontal line to line 4, and this will be another point on the curve. Do this to all the diagonals, and then you will find that all the points on the curve, when measured up, will give exactly the same value as when they were found by calculation. It will also be found that area of the parallelogram enclosed by the horizontal and vertical lines at each point will be the same wherever they are taken, thus proving that pressure x volume is always a constant. In the foregoing, we have considered only two quantities, that is pressure and volume, and we have considered that the expansion or compression of the gas has been carried out without either loss or gain of temperature.

Now we will go into this a little further, to make clear, what is meant by "neither loss or gain of temperature."

If a gas is compressed, it means that mechanical work has been performed on it, and this work will appear in the form of gas in the shape of heat, or added temperature. Now in order to fulfill the law of equal increases of pressure for decreases of volume, this added temperature must be dissipated, and the temperature kept uniform from start to finish of the compression. In order to do this, we must assume that the compression takes place in a perfectly conducting vessel, so that the heat of compression is conducted away as fast as it appears.

Now when we expand the gas back to its original volume, the energy necessary must come from the temperature or heat content of the gas itself, and in the ordinary way, would result in a lowering of temperature far below the starting point. In order to keep the gas within the limits of Boyle's law, we must then imagine that temperature is added from an outside source, to keep the gas at the same temperature from the start to the finish of expansion.

Adiabatic Expansion

It is hardly possible to obtain perfect isothermal expansion or compression in the heat engines in use, such as steam engines, or internal combustion engines. In air compression or gas compression such as are used in a refrigerating machine, an approach is made to isothermal compression by reason of the water jacket which absorbs and dissipates a proportion of the heat.

To understand adiabatic expansion we must assume that the expansion or compression takes place in a vessel which is perfectly insulated, and will not admit heat to pass through its walls in either direction from outside to inside, or vice versa. If we have such a condition, we shall then have all the heat of compression retained in the gas and, therefore the work done during compression is stored up in the gas ready to be given out on expansion.

We also have the condition that while the gas is expanding no heat can be added to it from any external source, and therefore all the heat of compression will be absorbed during expansion, so that we should arrive back at the same point from where we started as far as heat content is concerned. However, the curve traced will not be the same as that traced by the isothermal expansion and compression. We have stated that the isothermal curve represents the expansion or compression of a gas at constant temperature. Therefore if the expansion or compression does not take place at constant temperature as is the case in adiabatic expansion, the curve traced cannot be the same in both cases.

A homely illustration of the difference can be found in the ordinary bicycle or motor pump. Take the pump and move it slowly from end to end of its stroke, drawing in a charge of air, and then compress this air slowly by moving the pump back against the resistance of the air. There will be no difference in the temperature of the pump as observed by placing the hand on it. If the pump is worked slowly and deliberately for an indefinite time, there will be little or no increase in the temperature of the pump. This then is isothermal compression, the heat having carried off through the thin walls of the pump and radiated to the outside air. This is all right as long as the pump is worked very slowly.

Let us now work the pump as we would in the ordinary way when pumping up a tire, and we find that very speedily the barrel cylinder gets hot, so hot as to be uncomfortable to the touch. Here it is evident we are generating heat faster than the walls can radiate it to the outside air. We are approaching the condition of compression without loss of heat, though we do not realize it completely, owing to the thin walls of the chamber. We have taken something that is not quite adiabatic and not quite isothermal, but more nearly approaching the isothermal. If it were possible to compress the air absolutely adiabatically, we should probably set fire to the tire before we had it pumped up.

There is a second law dealing with compression or expansion of gases and that is the law of Charles, which states that if a gas is kept at constant volume, then each degree of temperature added to it, will increase its volume by a definite equal amount. Similarly, if a gas is allowed to expand, so as to remain always at the same pressure, then each degree of temperature added will bring an equal addition of volume.

This law is expressed by an equation similar to the equation of Boyle, but in this case taking the temperature into account. This temperature is also the temperature measured from absolute zero, and is the Fahrenheit temperature plus 459.5. or the Centigrade temperature plus 273. The equation is then

$$\frac{PV}{T} = \frac{P1\,P1}{T1} = \frac{P2\,V2}{T2} = R$$

or the quotient of the pressure multiplied by the volume and divided by the absolute temperature is always a constant, and this constant is represented by the letter R so that

$$\frac{PV}{T} = R$$

If we take a pound of air at the pressure of the atmosphere, and a temperature of 32, or 491.5 degrees absolute, we have, putting in figures in the formula

$$\frac{14.7 \times 144 \times 12.36}{491.5} = 53.37 \cdot$$

Then we have directly from this

$$PV = RT$$

or

$$14.7 \times 144 \times 12.36 = 53.37 \times 491.5$$

The increase of pressure per degree when the air is at constant volume, is not quite the same as the increase of volume per degree when the air is at constant pressure. In other words, the quantity of heat required to raise one lb. of air one degree is not the same when the air is kept at constant volume, as it is when the air is allowed to expand but is kept at constant pressure.

Fortunately we know the relations these two specific heats bear to one another. The specific heat of air when at constant volume, is .1685, and at constant pressure .2375. This means that to heat one pound of air one degree at constant pressure requires .2375 B. t. u.

The ratios of the one specific heat to the other is 1.408, and it is from this ratio that the adiabatic curve of expansion or compression is calculated. Thus instead of the P. V. C. of Boyle's law, or the $\frac{PV}{T} = R$ of Charles' law, a combination of the two is arrived at which gives an equation as follows:

$$PV^{1.408} = P1\,V1^{1.408} = P2\,72^{1.408}$$

which is the equation for adiabatic expansion.

The exponent will not be the same for all gases, but it varies slightly for steam, superheated steam, air, etc. The effect of the exponent is to make the curve of adiabatic expansion higher than that of the isothermal.

The relation of these two curves to the curve we get from an air ammonia compressor, or steam engine, can be now indicated. If we are compressing air our endeavor is to carry away the heat of compression as rapidly as possible from the cylinder walls, and if we are compressing ammonia or CO_2 in a refrigerating machine we also wish to carry away the heat of compression. This means then that we wish to have the curve obtained on an actual indicator diagram taken from these compressors approach the isothermal line as closely as possible.

If we are expanding steam in a steam engine cylinder we endeavor to insulate

Getting It Started

ON THE opposite page will be found a letter from Mr. Henry Wright, of Montreal, giving details of the action he has taken towards realizing the ideal of an uniform certificate throughout Canada. It would seem from this that the Province of Quebec is going to lead the way in this highly important matter, and be the first to take any definite action.

When we raised the question of a Dominion Wide Certificate in these columns it was because we felt, and always have felt, that the present arrangements were unfair, and hard on the engineer who wished to change his location. There were very many of our readers of the same opinion, and therefore, we have reason to hope that Mr. Wright will get active support from the engineers in other provinces.

As far as the engineers themselves are concerned, a scheme under jurisdiction of the various provincial governments, provided it is an uniform and co-operative arrangement, is just as satisfactory as the Dominion arrangement. It may be a little more expensive to carry on, but the revenue remains to the province, which will please the politicians.

We shall watch with great interest the progress of the negotiations between the different provinces, and we hope to see a lively interest taken in this subject by the engineers themselves, who, after all, are the most affected.

The C. A. S. E. Convention

THE ANNUAL convention of the Canadian Association of Stationary Engineers is only a little more than a month distant, and the delegates to the Grand Lodge will be chosen and instructed very soon now.

The C. A. S. E. has been in existence now for a period of thirty-three years, and during that time has some good things to its credit. It has the opportunity, if availed of, to make itself the representative association of the stationary engineer in Canada, which it is not at present. There seems, however, to be a spirit of progressiveness abroad in the Association, that augurs well for its future. The meetings in the various lodges have been dealing with matters that are instructive to the engineer in his daily work, and the educational side of the lodges' activities have been kept well to the fore.

If the association is going to be the force in future that it should be, it is absolutely necessary that it should attract a greater membership. It is also necessary that this membership should take an active part in its affairs. That the membership is such a small one in such a large field is somewhat of a source of wonder, and the fault must lie within the Association, and not without. We are inclined to think that one of the reasons is that the original form has been too strictly adhered to, and that what was possibly the best type of organization thirty odd years ago is not the best for to-day.

For instance, we think, and we advance these suggestions in all humility, that it is a mistake to mix up an engineering society with a secret society. There is no real connection between the two and the result is that a considerable amount of time is spent on ritual that might better be devoted to engineering matters. Most of us are affiliated with some fraternal or similar organization, and such affiliation does not interfere with our ability to become members of a professional or trade society.

Secondly, we believe it would be a good thing for the Association and the individual members thereof if the membership, like the certificate, was graded. That is full membership would only be granted to those men possessing a certain standard of experience and qualifications, those not possessing this standard, to be associate members. Thirdly, we believe that a man does not value what he gets too cheaply, and the financial standing of the Association should be enhanced by the increase of the annual dues, and entrance fee. By this means, it might become possible, in the larger centres at least, to have permanent rooms, instead of a room that is only open twice a month, and these rooms could be used as a sort of club room, and would be available for lectures, entertainments, etc., on any night required.

The Association would thus become more in the line of a professional society, and if conducted along these lines, would be a guarantee of a man's standing just as the larger professional societies are in their field. With the gradual tightening up of the regulations and the possible introduction of the interprovincial or universal certificate, the privilege of being a member of a strong Association would be sought after.

It seems to us that there would be no difficulty in working out the details of such a scheme, and there are enough capable men within the C.A.S.E. at present to form a strong executive.

It might be necessary to get a new charter, but this would not prove a very difficult matter.

Whatever the form takes, we do not doubt that some drastic change will have to be made, because an organization that stands still cannot be a permanent one. The best friends of the C. A. S. E. are not satisfied with its present status, and rightly so.

The coming convention is the place to take up these matters.

A Move For The Universal Certificate

THE RECENT discussion which went on in the columns of this Journal on the advisability or otherwise of having a certificate of uniform value throughout the Dominion, caused a great deal of interest, and has resulted in some action being taken. The majority of those who expressed opinions were favorable to the idea, and Mr. Henry Wright of Montreal, has gone further than merely expressing an opinion. He has taken some active steps towards realising the idea as the following letter from him will show:

The Editor,
Power House.

May I ask you to publish the following for the benefit of all those who are interested in the Dominion-wide Certificate, as it has been called during the discussions recently carried on in your columns.

I would point out in the first place, that "Dominion-wide Certificate" is not the correct name, and if the scheme should go through, the certificates will not be known in that way. The name will have to be "Inter-Provincial" rather than "Dominion," because the provincial Governments will not submit to what they might look on as interference from the Federal Government in their domestic affairs. The engineers' license from their point of view is simply a matter of dollars and cents, and they will look askance at any scheme that threatens to remove a source of revenue from the provincial treasury.

I have had an interview with the Minister of Labor for the Province of Quebec, who is greatly interested in the Inter-Provincial Boiler and Engineer's laws, as they will be known in future, and he gave me to understand that any interference from Ottawa would be met with disapproval, and that the majority of the Ministers were of the same mind.

He was going to meet the Minister of Labor for Ontario and talk the matter over, and said he would see me on his return. To make doubly sure of this, I am trying to get the Canadian Manufacturers' Association to give the engineers their able support, which I think they will do.

A brief outline of the scheme as I gave it to the Minister would perhaps help those who may be working along the same lines in Western Canada. I would ask every province to have the same standard in their examination and get away from the petty quibbling that one examination is harder than another, and make it all one examination. I do not mean by this that everyone would have to be examined again, but if the Inter-Provincial examination became a fact, the examiners could arrange for the examination for new candidates.

The method of working the law would be as follows: If an engineer wished to leave the Province of Quebec, and take up a position in Ontario, he would apply, either personally or by mail, to the examiner in Quebec, for an identification card. This card would be in triplicate, one copy of which goes to the engineer, the second one is sent to the examiner in the province to which the man is going, and the third one is kept on file in the province in which he was examined. When he reaches Ontario, he notifies the examiner, and produces his identification card, which on being compared with the copy in the Ontario examiner's possession, and being found correct, entitles the holder to a permit of the same grade for as long as he wishes to remain in the province.

If he should wish to return or go to another province at some future time, he will notify the Ontario examiner, and surrender his permit, when the identification card will be again issued to him, and a copy sent to the place he is going to.

The yearly fee will be paid as usual. It will hardly be possible to get away from this, as it is a source of revenue to the province, and under this scheme, the province in which the man is working will get the revenue. Then again, an engineer can be traced from province to province by means of his identification card, and wherever he passes his examination, there his papers remain for reference at any time. He may pass for third in one province, second in another, and first in still another, his identification card from each one proving his eligibility to sit for the higher grade.

I am writing to the Ministers in the other provinces, but at the same time I should like someone in each province to help me in this work which I feel will be appreciated by the engineers in the years to come. I might add that the scheme would make it possible to keep track of a man should he drop out of the game for a few years, and want to steal back to it. His last identity card will give all the information. In the same way, a man could not steal from one province to another, without going through the necessary formalities.

Now, Mr. Editor, the reason I am writing this letter is to let the engineers in other parts know what I am doing, so that they can be aware of the developments as they take place. Any questions which may be asked I shall be pleased to give information on, so that anyone interested can take up the work in any other province.

Thanking you for the space you have given me.

Henry Wright, A.M.I.C.
Chief Engineer,
Montreal Tramways Hochelaga Power Plant.

Editor's Note

The scheme outlined by Mr. Wright seems to be one that will have a good chance of being adopted, and though we would personally rather have seen the whole thing under the Federal Government, we recognize the force of the argument as to Provincial revenues. Provincial governments generally need every cent they can raise, and they are the last ones to dream of cutting off any possible channel of wealth. The proposed arrangement would give as far as we can see a perfectly fair deal to everyone, and should be welcomed by the employer, as it will give him a certain guarantee of the kind of man he is getting, when the man is a stranger in the province. It will save a man the trouble and expense of going up for examination whenever he makes a move, and also ensures that he will not lose the benefit of his years of experience in one province when he moves to another.

Mr. Wright deserves the thanks of his fellow engineers for the time and trouble which he has given to this matter, in their interests, because there is very little probability that he would ever be personally affected by it.

We shall be glad to open the columns of Power House to those who wish to offer suggestions or comment in any way on the subject.

OUR QUESTION BOX

Questions are invited from readers regarding power plant operation and difficulties encountered

SETTING OF BOILERS

Question:—Is there any law regulating the setting of horizontal return tube boilers in Ontario? I am told that these boilers should always have a rake towards the back end of ½ inch for every four feet of length. Is this correct, and if so why should it be?

Answer:—The setting of horizontal return tube boilers follows a fairly standard design, the great difference being in the height that the boiler is set above the grates by different designers, or installers. The only regulations are those that refer to the method of suspension, and the minimum width of combustion space, that is distance from back tube plate to back wall. It is usual to set h. r. t. boilers with a slope towards the back end of the boiler, as this is of great assistance when the boiler is being washed out, and when the boiler is working it ensures an ample depth of water above the tubes at the back end when the water in the glass is just bobbing in the nut. As the bottom nut of the gauge glass is usually about four inches above the top row of tubes, this would give at least six inches over the tubes at the back end.

SUCTION AND CONDENSER

Question:—In running an ammonia compressor at 200 r. p. m. what advantage if any is there in carrying a low or high discharge temperature, or what should the discharge temperature be at 25 lbs. back pressure and 165 lbs. head pressure with condenser water at 65 degrees?

Answer:—In operating an ammonia compressor the suction pressure and discharge pressure should be as close together as possible, consistent with maintaining the desired temperatures. The refrigerating effect depends on the amount of gas handled per hour, and the temperature it reaches the evaporator at. If the suction pressure is very low, it means that the gas occupies a large volume, and a less weight of gas per stroke can be handled. If the discharge pressure is high, the machine has to do more work in compressing the gas. The temperature corresponding to a pressure of 25 lbs. per square inch on the suction side is 10 degrees, but if this is 25 lbs. absolute the temperature is about minus 5 degrees. The temperature corresponding to 165 lbs., gauge [illegible], while that corresponding to 165 lbs. absolute is about 83 degrees. Assuming that all the heat or nearly all the heat of compression is removed by the circulating water, or the evaporation of the liquid in wet compression, the gas will leave the compressor at a temperature of between 98 and 100 degrees, and if there is sufficient circulating water passing through the condenser the temperature of the liquid reaching the receiever should be about 75 degrees with circulating water entering at 65 degrees.

Assuming that the pressures given are gauge pressures, then the volume of one lb. of ammonia at 25 lbs. gauge is 6.583 cubic feet. The latent heat at the evaporator pressure is 560 B. t. u. and as the temperature of the liquid going to the evaporator is 75 degrees, the liquid will have to give up to the brine 60 degrees before evaporation takes place. Deducting this from the latent heat this leaves 500 B. t. u. per lb. of ammonia circulated as the cooling effect. Then in order to perform one ton of refrigeration per hour, which is equal to 24,000 B. t. u. per hour, there will have to be circulated 48 lbs. ammonia per hour, or .8 lbs. per minute, or 5.26 cubic feet ammonia per minute.

AIR AND STEAM EXPANSION

Question:—In considering the possibility of an air turbine, I have got the idea that it is impossible to use air for this purpose, because air in expanding through a nozzle does not change heat into velocity the same as steam does. Then again I have read that in the liquefaction of air free expansion is used to lower the temperature. What is the explanation of this?

Answer:—The energy contained in one pound of steam is that due to the total heat, or sensible heat plus latent heat, and in the case of steam at atmospheric pressure, this would amount to 1,146 B. t. u. or 1,146 x 778 or 891,558 ft. lbs. In the case of steam at 150 lbs. pressure the total energy due to its heat content would be 1,194 B.t.u. or 928,932 ft. lbs. If steam is allowed to expand freely without doing work its heat content at the end of expansion will be practically the same as at the beginning, the result being that the steam is slightly superheated. Now by far the greater portion of the energy contained in steam is that due to its latent heat, and when it has dropped to atmospheric pressure, the latent heat is more than it was at the higher pressure, although the total heat content will be less. Some heat will have been lost due to radiation, but this is a small amount, and practically the whole of the energy of the steam at 150 lbs. pressure will be available to be turned into velocity at the mouth of the nozzle. It will be seen then that the influence of temperature is far less than that of the latent heat.

When we are dealing with air it is another matter. The total energy of any perfect gas is entirely due to its absolute temperature, or as it is expressed in Charl's law, "Equal increments of temperature give equal increments of volume, at constant pressure, and of pressure at constant volume." That is, its capability of doing work is entirely dependent on its absolute temperature. It possesses no latent heat as in the case of steam. Therefore if we allow air to expand against the pressure of the atmosphere, the energy necessary is obtained from its temperature. In the case of air the energy available per round is 52.37 x abs. temperature. Take one pound of air at atmospheric pressure and temperature, its energy is represented by the equation

$$PV = RT$$

where P is absolute pressure per sq. ft. V is volume in cubic feet, and T is absolute temperature, R being the constant for air 53.37, and if atmospheric temperature is 32, the 53.37 x 491.5 gives 26,163 ft. lbs.

Compare this with the energy in one pound of steam at the same pressure.

Now take one pound of air which has been heated at constant volume until the pressure is 165 lbs. absolute. The temperature corresponding to this will be found from

$$\frac{P2}{P1} = \frac{T2}{T1}$$

and

$$\frac{165}{147.5} = \frac{T2}{491.5}$$

Then

$$T_2 = \frac{165 \times 491.5}{14.7}$$

$$= 5504.8$$

and the available energy at that pressure and temperature would be 53.37 x 5504.8 = 293801.396.

The work done in expanding freely

from the pressure of 165 lbs. abs. to 14.7 abs. is p $(v_2 - v_1)$
where p is the main pressure during expansion. As the ratio of expansion is $\frac{165}{14.7} = 11.2$ the main effective pressure would be approximately 49.5. The initial volume would be $\frac{12.36}{11.2} = 1.1$ and then we should have 49.5 x 144 as the P and 12.36 — 1.1 = 11.26 as V and work done
49.5 x 144 x 11.26 = 79135.

This amount of work would be performed at the expense of the temperature in the gas. However, when we have expanded down to atmospheric pressure it is obvious we can make no further use of the temperature energy of the gas, as we cannot expand below atmospheric pressure, as in the case of the turbine.

It is therefore obvious that the use of air as a working medium in a turbine is hardly practicable.

The equations above are of course only approximate. Air under compression follows the law PV = C, and in the figures we have not taken the exponent into account.

AN APPRECIATIVE SUBSCRIBER

It is not often we allow our native modesty to be overcome, but we feel that in the light of the expressed wish of our correspondent to publish his letter, we have a good excuse to get in the limelight. The letter follows:

Chilliwack, B. C.,
April 28, 1922.

Editor, Power House,
Dear Sir:

I received your letter yesterday and I must say I was very surprised, though highly pleased, to think what an interest both you and the Power House take in the engineer and his vocation. I have been a reader of the journal now for more than three years, and I may say that the Power House has become indispensable to me.

On the evening of its arrival every other piece of literature is put away until the contents are fully digested and salted down to be used on the job as soon as possible.

The parts of the paper that I am most interested in are the descriptions of new equipment and also descriptions of large plants in the East. I thought a great deal of the article describing Mr. Henry Wright's plant at Hochelaga. I think that these articles are very good, as it tends to bring the engineers together and also lets the Western men see how it is done in the East. I would like very much to meet Mr. Wright and men of his stamp, as I know they would prove very interesting to the young engineer and I think there is no better way of getting acquainted with these gentlemen than through the pages of the Power House. "The Question Box" is also very highly thought of by me and also the power plant kinks are very useful. But what comes first and foremost with me is the description of accidents such as boiler and fly wheel failures, water hammer, etc. These things are happening every day, and although how careful a man may be they will happen to the best, so I think no matter how small these things are they should be published and then they could be guarded against.

Your correspondence department always gives me great pleasure and I enjoyed the Dominion-wide certificate discussion and I am very glad to see that the majority were for it, as it tends to help the engineer a whole lot.

You mentioned advertising. I have heard several men say that you carried too much, but that is wrong. If every engineer would take advantage of the descriptive literature that these firms have to offer they would benefit greatly by it. I have sent for literature on various things such as meters, draft gauges, traps, packing, etc. It was not very long before I could put that information to good use, so I think that any man that downs advertising is making a very grave mistake as there is a lot of free information there for the asking and it is every engineer's duty to follow it up because he may never know when he may be called upon to use it.

Taking your journal on the whole I am highly satisfied with it and I think it is 100% efficient and the engineer of today is needing just such a paper. Engineering is a fine trade for a young man who takes it, and is willing to forge ahead. It holds some wonderful possibilities. But it is a very poor one for the man who only wants to know enough to get by on as every engineer knows that no man has to put up with more and works harder than the engineer of a "hay wire" power plant, and that is the place where these men will find themselves as the modern power plant only wants the man who is willing to take an interest and get ahead, so I think it is the duty of every Canadian engineer to subscribe to the only Canadian engineering journal in Canada, and boost it to the limit.

Hoping you will find room to publish this letter in your paper, as I should like some of the engineers to see that we are satisfied with the Power House in the West. Thanking you for the trouble you took in writing me, and wishing the Power House a fine future and every success, I remain

Yours fraternally,
John P. Kingscote.

A NEW TYPE OF PUMP

We had the privilege recently of witnessing a demonstration of a new steam pump designed by Mr. Atwood of Toronto, and manufactured under his direction by the Atlas Engineering Works of this city. The novelty of the pump lies in the water end, and a radical departure from the usual design is apparent here.

Instead of the usual two decks, containing suction and discharge valves these valves are concentrated in one deck. The cages containing the valves and valve seats fit loosely into the casting, and are held in place by dogs, which in turn are held down by cap screws in the pump chest cover. This arrangement makes it possible for any valve and valve seat to be lifted out bodily after the cover is removed, and any repairs required can be performed in ease and comfort on the bench. The flow of water through the pump can be reversed by simply removing the suction valves and putting the delivery valves in the place, the suction valves taking the place of the delivery, and this change can be accomplished in a couple of minutes.

The arrangement reduces the clearance space in the water end considerably which tends to the efficiency of the pump. The water passages are at the same time freer than in the ordinary design. The pump acted very well on its trials, and the absolutely positive action of the steam valve was demonstrated, it being impossible to stop the pump as long as the steam was turned on. This is of course a very important feature in a simplex pump. The steam valve is also designed by Mr. Atwood. In a future issue we hope to give particulars of this pump, which makes a decided advance in steam pump design.

THE IMPORTANCE OF EMERGENCY CLOSING VALVES

(Continued from Page 24)

breakers, so that the overspeed governor can be tested when necessary, or the oil pressure and steam pressure can be built up without tripping the emergency closing valve.

One type of diaphragm contact breaker is shown in Fig. 6. This is a device whereby a diminution in pressure is utilized to cause a movement of the diaphragm to open an electric circuit,—thereby breaking the circuit through the magnet of the emergency closing valve releasing the swing weight, and tripping the valve shut. Other arrangements and types of pressure control apparatus have been utilized. The one shown is merely typical.

As stated above, the emergency closing valve can be made to close either when the steam pressure in the steam supply pipe to the turbine falls any predetermined amount below the minimum allowable operating pressure, or when the pressure of the lubricating oil becomes dangerously low, or finally, when the turbine overspeeds. It insures instant automatic protection and its importance as a secondary protection for large turbine units cannot be overemphasized.

Practical Electricity for the Power Plant Engineer

By G. R. ARCHDEACON, A.M.I.E.E.

Chapter V

HAVING recently considered the various factors encountered in all electrical circuits, such as current density, voltage, drop heating effect, economical cross sectional area, power in circuit, etc. Let us now briefly consider some practical aspects of the methods of distributing the current by means of a simple wiring system.

Whenever it is desired to instal a system of wiring, either for light or power, it is necessary that a careful survey should be made of the proposed location of the various wires and cables. Special attention should be paid to the accessibility of the wires after installation, whether the location is exposed to the weather, steam, chemical fumes, etc.

Having chosen suitable locations, attention must be paid to the quality of the insulation of the wire and cable, if the location is ideal, then a lower quality of insulation may be employed, resulting in a saving in purchase price of the wire. If on the other hand the location of necessity is exposed to the various elements above suggested, then only the very best class of insulation can be considered.

The insulating material covering the wires or cables, should possess high specific resistance, mechanical strength and flexibility, retentivity of insulating values under changes of temperature and contact with acids, gases and fumes.

As an indication of the wide range existing between the resistance of various coverings employed to insulate the wires it is only necessary to bear in mind that the specific resistance of high insulating rubber is approximately 16,000, this becoming gradually less in the various substitutes for rubber until we get down to as low as only 250 Ohms specific resistance.

Therefore it will be apparent that the quality of the insulation must be carefully considered, and just how suitable it would be for the proposed location in which it is intended to be installed.

Before proceeding with any extensive scheme of wiring it is advisable to call in the local electric light and power authorities, and discuss with them their various rules and regulations controlling wiring systems, and carefully study their by-laws governing the same. By so doing you engender their good will, and will secure yourself against any disappointment after the job is completed, either from the fire underwriters, or the local authorities.

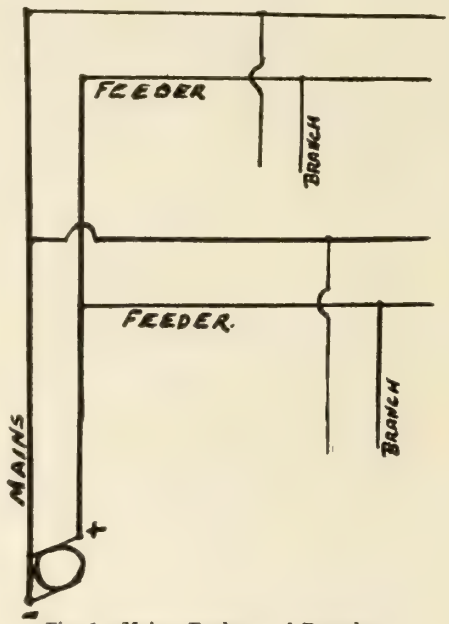

Fig. 1.—Mains, Feeders and Branches.

Elements of a Wiring System

In any wiring system, there are three fundamental elements entering into its construction. These are, mains, feeders, and branches.

Mains are the principal wires connecting the source of supply to the system. These have to carry the major portion of the total current used on the system, and frequently they have to carry the whole of the total current used.

The most careful calculation is therefore necessary in choosing the correct sectional area, thereby preventing any undue loss of power throughout the system.

Feeders are of smaller sectional area than the mains, and are tappings taken off the mains at suitable points along the route of the mains.

Branches are of still smaller sectional area than the feeders and are the parts of the circuit with which we are all more familiar, as it is directly from them that we take our wires for the lamps, toasters, irons, etc. A simple development of these three elements is shown in Fig. (1).

In laying out any wiring system it is of the greatest importance that definite fixed points should be established (after careful calculation) for provisions of centres of distribution, and to such points the mains should be taken and the current distributed therefrom.

As already explained, along any wire of equal cross sectional area throughout its length, and of similar material, the drop of volts will be evenly distributed throughout its entire length. That is to say, suppose the wire in question was carrying a given amount of current, and its length was 1,000 feet., if the voltage drop over the total length was 10 volts, it would only be 5 volts at 500 ft., etc.

It will therefore be apparent that instead of connecting the main to one end of such a wire, if we connected the main to the exact centre of the wire, the current would only have to flow 500 ft. from its source of supply, hence the voltage drop would be halved. This would be the centre of distribution, and can of course be again divided in various sub-centres as required, the idea being to so arrange these centres of distribution so that the pressures in the various heavily loaded circuits are equalized.

So far we have only considered a system that was supplied with only two mains, but there is also another system which provides three mains, this being known as the three wire system. There was also a five wire system developed by the late Dr. Hopkinson of the Manchester University, Eng. The system was employed on the Manchester Corporation Electricity Dept., but after several years "try out" was gradually discarded owing to its many complications, and

Electric Cranes

We manufacture high class Electric Cranes of every type and for every purpose.

Overhead Travelling Cranes for the most onerous work of lifting a complete locomotive or for the exact work of handling moulds and molten metal and for ordinary requirements where lightness and speed count most.

Giant, Goliath, Gantry and Transporter Cranes for shipyards, railway yards, and general manufacturing purposes.

Electric Portal Jib Cranes fitted with Patent Balanced Lever-Luffing Jibs

Travelling and Stationary Jib Cranes with fixed radius jibs or fitted with Patent Balanced Lever-Luffing Jibs for use on docks, in shipbuilding yards and other places where the load must be handled at speed between obstructions that necessitate the radius to be altered frequently and as a part of the "cycle of operations."

SHEER LEGS to which Luffing-Jib may be applied.

CHARGING MACHINES for Open Hearth and Re-heating Furnaces.

ELECTRIC CAPSTANS

WINCHES AND HOISTS

Conveyors

for handling raw materials such as coal, coke, ashes, clinker, ore, stone, lime, etc., automatically and with a minimum of labour.

The B. & W. line of Mechanical Handling Machinery includes Bucket & Tray Conveyors, Suction Ash Conveyors, Automatic Railways, and all the details thereof including coal and coke breakers, loaders, dumpers, weighing machines, etc.

We shall much appreciate an opportunity of going fully into details of any of our manufactures with intending purchasers.

BABCOCK & WILCOX, Limited

HEAD OFFICE FOR CANADA COLLEGE ST. (ST. HENRY), MONTREAL

TORONTO OFFICE, BANK OF HAMILTON BUILDING

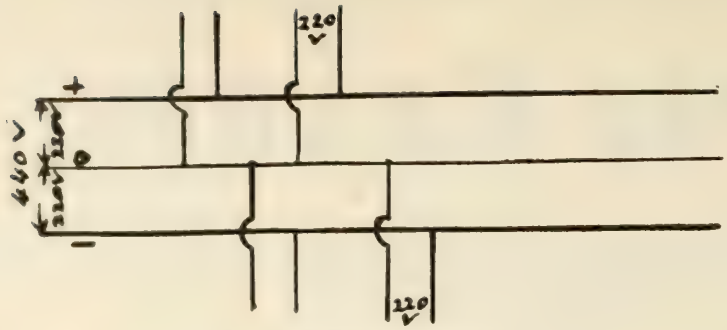

Fig. 2.—Three Wire Distribution.

has been entirely superseded by the more convenient three wire system.

Three Wire System

This is the most modern and the most generally employed system in operation in the distribution of electric power, and is equally adapted for A.C. as well as D.C.

The distribution is effected by means of three mains (Fig. 11), two of the wires are called the outers, whilst the third wire which is arranged between the two outers is called the middle wire or neutral wire.

The outer wires are called the positive outer and the negative outer respectively, and they are twice the sectional area of the middle wire.

The pressure between the outers is twice the voltage of that between the middle wire and either one of the outers. Suppose the voltage between the outers was 440 volts the voltage between the middle and either of the outers would be only 220 volts.

For the ordinary lighting services two wires are taken, one from one of the outers and one from the middle wire, but for the operation of motors, etc., the two wires are taken only from the two outers.

It will be apparent that if all the load was connected, say between the positive outer and the middle wire, the system would be out of balance. Care must therefore be taken to see that each side of the system is equally loaded up. It is not possible in practice to maintain this balance, the system is always out of balance to some extent, and the middle wire is the pathway for the current that is out of balance.

The middle wire must therefore perform the function of a positive wire when the out of balance current comes from one side of the system, and then act as a negative wire when the out of balance current comes from the other side. (Fig. 111).

The greatest advantage of the three wire system over the two wire system is the economy in wire and cable, as it permits a given amount of power to be distributed with about one third the amount of copper that would be necessary on a two wire system.

Consequently the cost of distribution is reduced, as the pressure on the mains may be twice the voltage generally used inside buildings for lighting purposes, this in turn reduces the amperage of such circuits by one half.

Suppose for instance in the case of a two wire system the lighting voltage was 220. The system could be raised to 440 volts for the purpose of running large motors in the building. This would not interfere with the present lighting system, as the 220 volts would still be obtained between the outer and the middle wires.

The reason for using higher voltages on the motor supply is because by doubling the voltage, for any given h.p. the current required will be halved. Another important point to remember is that when the motor is connected across the outers, switching on or off does not affect the volts in the middle wire, consequently there is no disturbance of the lamps connected to the middle wire. Whereas if the said motor was connected between the outer and the middle wire, there would be a rush of current on one side of the system as to so completely render it out of balance that one side of the system would be getting scarcely any voltage through their lamps, with consequent loss of illumination, whilst the opposite side of the system would be getting too many volts resulting in the burning out of their lamps.

It is worth while to just pause a little and consider the reason of the economy involved in using higher voltage for the motor service.

The weight of copper required for the transmission of a given amount of electric power is inversely proportional to the square of the pressure.

Mr. Newton Harrison (in his book on this subject) has prepared a table which demonstrates the above postulate in no uncertain manner. A copy of this is herewith given.

Volts	Circular Mils.	Kilo-Watts.	Length of Wire Ft.	Weight of Wire, Lbs.	Drop Volts.
100	440,000	100	2,000	2,666	5
200	110,000	100	2,000	667	10
400	27,500	100	2,000	167	20
800	6,875	100	2,000	42	40
1,000	4,400	100	2,000	7	50
2,000	1,100	100	2,000	7	100

From an inspection of the above table it will be seen that when transmitting 100 kws a distance of 1,000 ft. it requires 2,666 lbs. of copper for a 5% drop, where as if we increased out voltage to 1,000 volts we only require 27 lbs. of copper. We have only increased the voltage 10 times, yet it has reduced the weight of copper 100 times.

It will therefore be apparent that there is somewhat of an analogy between the economy in the employment of high voltages, as there is in the use of high pressure steam.

When the system of wiring has been decided upon and the installation of same completed, it is necessary to repeatedly have it tested to discover whether any leaks have developed, either through faulty workmanship, or material, or perhaps from some special causes such as acid fumes, steam, water overloading, or too high voltages or other contributory causes.

These tests are generally such as to determine the value of the insulation resistance, this resistance being measured as between—

(a) The earth and the positive wire.

(b) The earth and the negative wire.

(c) The resistance between positive and negative wires.

It will readily be understood that it is practically impossible to entirely eliminate leakage through the insulation, there is always a certain amount taking place, in large power houses the "units unaccounted for" amount to quite large figures, although comparatively small when compared with the total units generated.

It will therefore be obvious that the higher the insulation resistance, the lower will be the "units unaccounted for" as the fewer units will leak through the resistance and become lost without having accomplished any useful work.

As it is impossible to entirely prevent leakage, it is necessary that some safe definite limit should be fixed. This generally is done by the local electric power authority, or the fire insurance underwriters.

In Europe electrical insurance is a very large portion of total industrial insurance, and electrical inspectors visit the various factories at regular intervals, in a similar manner to the boiler inspector, just to "check up" this condition of the insulation resistance.

Many and varied are the instruments used in the making of these insulation tests, the modern tendency is to make the thing so simple and mechanical, and to free the process from all mathematical calculation (apparently to permit of the employment of cheap labour) that such instruments are now extremely delicate, and likewise extremely costly.

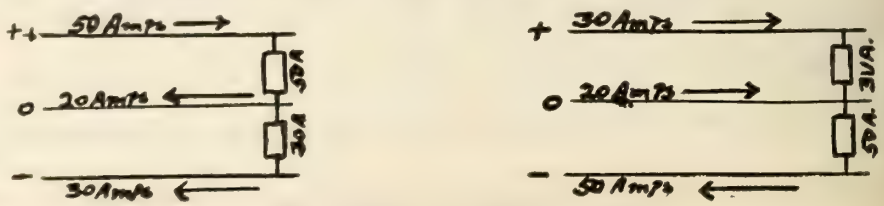

Fig. 3.—Direction of Unbalanced Current.

THE DICTIONARY OF APPLIED PHYSICS

Five Volumes Fully Illustrated

edited by Sir Richard Glazebrook, K.C.B., D.Sc., F.R.S.

VOL. I.—MECHANICS—ENGINEERING AND HEAT
VOL. II.—ELECTRICITY.
VOL. III.—METEOROLOGY, METROLOGY, AND MEASURING APPARATUS.
VOL. IV.—OPTICS, SOUND, AND RADIOLOGY.
VOL. V.—METALLURGY AND AERONAUTICS.

It is our privilege to announce the most comprehensive and important work on its subject yet published. A Dictionary of Applied Physics in five volumes.

The first attempt which has been made to bring within the compass of a single work the latest results of research, and the most approved methods in all branches of Applied Physics.

A unique work of reference, containing a mine of information invaluable, not only to those engaged in professional work, but also to manufacturers, who are concerned with the question of Physics as applied to Industry.

Applied Physics is a comprehensive subject and the task of gathering the applications has been difficult. The dictionary will appear in five volumes of 800 to 1,000 pages each, and the Editor has secured contributions from the most competent authorities in Great Britain and America.

The volumes have been arranged as far as possible in subjects. The arrangement in each volume is alphabetical, but each main subject is dealt with in a continuous article, reference being given, each in its alphabetical position to the headings of the various sections of an article and the subject it includes.

You will no doubt be keenly interested in this valuable and unique work, which has long been needed by Industry and Science, and we would like to send you further particulars. If you will sign the attached coupon, this additional information will be sent. It does not obligate you in any way whatever.

NAME ....

ADDRESS ....

However, accurate results can be obtained by the use of a high resistance voltmeter, a spirit of confidence in the eternal verities of Ohm's law, the application of a little thought, and a few simple arithmetical calculations.

Let us therefore tackle one or two examples.

First obtain a high resistance voltmeter, the resistance of which must be known. Suppose this turns out to be 20,000 Ohms.

What are we out to find? How much current is leaking from a certain wire.

What will be the use of a voltmeter when we desire to measure current?

All instruments consume current in the moving of some part of its mechanism (except special electrostatic instruments). Therefore some current is consumed in causing the needle of the voltmeter to move over the scale. Naturally the further the needle moves over the scale the more current it will consume. Therefore the voltmeter is nothing more nor less than a very low reading ammeter. Therefore we can read current values on a voltmeter. But to convey to us any exact knowledge of the amount of current flowing through the voltmeter we must know its resistance. In all high class instruments, the resistance is generally given on a card supplied with the instrument, such card being the certificate of calibration from the testing dept. of the manufacturer.

Let us therefore assume that the resistance is given as 20,000 Ohms. We therefore proceed as follows:—

First Test

To find the circuit voltage.

Connect the voltmeter to the positive and negative poles of the circuit. This will show the voltage between these two wires. Let this pressure be called E, and if E shows 200 volts on the instrument, it may be considered as that small quantity of current which registers 200 divisions on the scale of that particular instrument.

Second Test

Find insulation resistance between the positive wire and the earth.

Connect one side of the voltmeter to the positive wires of the source of supply.

Connect the other side of the voltmeter to the circuit to be tested (first seeing that the circuit to be tested is disconnected from the source of supply).

Connect the negative side of the source of supply to earth.

Let us now consider what we have done. We have simply interposed between the positive pole of the source of supply, and its corresponding negative pole, a resistance of 20,000 Ohms which is again placed in series with the resistance of the insulation of the wires under test. Providing there is no "dead earth" the deflection now obtained on the voltmeter will be considerably less than in the first test because whilst the voltage has remained constant at 200 volts, the resistance of the circuit has been increased from 20,000 Ohms to an amount greater by the value of the resistance of the insulation. Consequently the current passing through the voltmeter will be reduced resulting in a corresponding reduction in the deflection of the needle. All this being a further verification of the truth of Ohm's law.

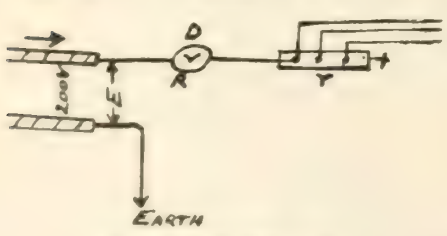

Fig. 4.—Insulation Test.

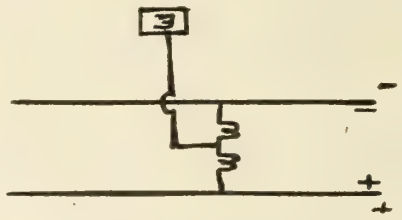
Let us now consider the results of this test.

Let E=Supply voltage=200 volts.

Let R=Resistance of voltmeter=20,000 Ohms.

Let r=Resistance of Insulation.

Let D=Deflection of voltmeter, say 40 divisions.



Leakage Indicator

Assuming in the above test the deflection was 40 divisions, remembering the voltage being constant, the deflection of the voltmeter will be directly proportional to the amount of current passing through it, and therefore inversely proportional to the total resistance.

Therefore—D : E : : R : + r

D would be equal to E if R only were in the circuit, because it would indicate E volts, but the more the resistance of the insulation, the greater the value of r thereby increasing the total resistance R r consequently the value of the deflection D will be reduced.

$$\text{Therefore—} R + r = \frac{E \times R}{D}$$

$$r = \frac{E \times R}{D} - R$$

Substituting the readings obtained we have—

$$r = \frac{200 \times 20{,}000}{40} - 20{,}000$$

$$= 100{,}000 - 20{,}000$$

$$= 80{,}000 \text{ Ohms.}$$

$$= .08 \text{ Megohm.}$$

This would represent the value of the insulation resistance of the circuit tested.

Such a comparative low value would not be considered satisfactory on a simple circuit containing a few lamps, but would be acceptable as a test on the whole of the installation where there were several motors included in the circuit.

Third Test

To find the insulation resistance between the negative wire and the earth.

In this test the supply pressure E is connected to the negative wire of the circuit under test, and the readings and calculations made as in the second test.

Fourth Test

To find the insulation resistance between the whole circuit and the earth.

This is merely a "check test." In this case the positive and negative wires are connected together, and then to the supply pressure E. and readings and calculations made as before.

It is always a sound principle to adopt on any installation, to make up a book containing details of the various mains, feeders, branches, and at regular intervals, say every 3 months to make a complete set of insulation tests, thereby always being in a position to lay your finger upon the defective wire in case of some emergency, when a "dead short" has suddenly developed.

A simple leakage indicator can easily be constructed and mounted on the main switchboard, this could be connected across the main buss bars or across the various mains running from the switchboard, through a small "change over" switch permitting it to be changed over from one set of mains to another, so making it possible to rapidly obtain an indication of any leakage that may be developing.

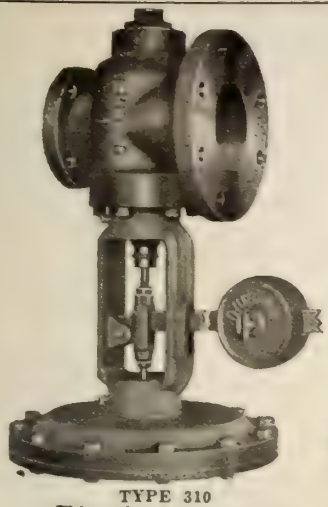
This leakage indicator is made up by connecting two ordinary carbon filament lamps in series across the mains, taking a tapping from the centre point between the two lamps and connecting it to earth.

The voltage of each lamp should equal that of the supply, so that each lamp only gets half its normal voltage, and therefore only just shows a dull red glow when connected in series. When the earth connection is made, providing there is no excessive leakage, both lamps will glow equally.

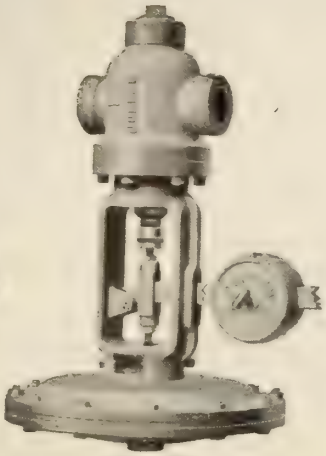
If any excessive leakage develops on one of the mains, one of the lamps will begin to glow brightly, whilst the other one will lose its red glow entirely. The change so brought about by these altered conditions, will immediately attract the attention to the attendant in the engine room.

The leakage will be on the main to which the darkened lamp is directly connected.

Montreal, Que:—Hart and Tuckwell, 163 McGill St., will erect a warehouse costing $20,000. Cook and Leitch, 358 Beaver Hall Hill, have been given the general contract.



TYPE 310
(This valve has increased outlet.)



Type 300

The DUNHAM HEATING SERVICE
(*Made in Canada*)

DUNHAM REDUCING PRESSURE VALVES

The Dunham Line of Reducing Pressure Valves is the result of many years experience in the manufacture of steam-handling specialties. They are worthy additions to the Dunham Line.

Dunham Reducing Pressure Valves are applicable to a wide range of initial pressures of steam, air, water, etc. They will reduce to the desired low pressure in one step, without chattering and are very sensitive in meeting sudden demands. The low pressure is evenly maintained, even though there be considerable variation on the high pressure side of the valve.

Regulation is by a lever and weight which may be set at any low pressure. Each instrument has a double balanced inner valve and seats of special phosphor bronze.

Full particulars will be sent upon request.

CATALOGUES

The Reliance Gauge Column Co., have issued circulars describing their high and low water alarm gauge columns. These alarms are operated to give an audible signal by a whistle, or a visible signal by electric light, or both.

We have received from the Canadian Ingersoll Rand Co., Montreal, a bulletin describing their type 15 vertical belt-driven air compressors, and the same type arranged for geared drive from an electric motor. The compressors are of the vertical single-stage, single-acting, self-oiling centre crank type, entirely enclosed. They are made in three sizes, 3 x 3, 3½ x 4, and 4½ x 5 inches. Complete sectional views of the compressor are given in the bulletin, as well as some of the constructive details.

We have received from the Lebanon Boiler Works Bulletin 21, describing their Uniflow boiler. In this boiler, which is of the horizontal tube type, the tubes instead of being arranged in the usual manner, are arranged in three separate groups, having a space between each group. Circulation is upwards between the tubes, while the downward circulation takes place between the groups of tubes in the comparatively large space left there. The firm's address is Lebanon Boiler Works, Philadelphia, Pa.

OMISSION

In the advertisement of D. K. McLaren, Ltd., in the issue of May 5th the addresses of the firm's agencies were inadvertently omitted. In addition to, the head office at 351 St. James St., Montreal, the firm are represented at 194 King St. W., Toronto, and 90 German St., St. John, N. B., under their own name, and by Gormans, Ltd., at 1158 Homer Street, Vancouver, B. C., Edmonton, Alta., and Calgary, Alta.

We have received from the Anderson Foundry & Machine Co., Anderson, Ind., bulletin No. 23 describing the Anderson oil engines. This bulletin describes in detail the construction of these units, which are built in sizes from 1 cylinder 30 h. p., to 6 cylinder 330 h. p. They are of the semi-Diesel type, and are recommended for all ordinary power generation uses.

Indian Air Pump Co., have issued a catalogue describing their pumping equipments for deep well purposes. A general description of the air lift pump, is given, with illustrations of the details of the heads, etc., and some typical installations are illustrated. A glossary of terms used in air lift pumping is included. The Indiana Air Pump Co. is located at Indianapolis, Ind.

ENGINEERING DICTIONARY

The first volume of a most important work, "A Dictionary of Applied Physics," edited under the supervision of Sir Richard Glazebrooke, K. C. B., F. R. S., will be ready for Canadian distribution about June 1st by the Macmillan Company of Canada, Limited, Toronto.

This valuable work will be published in five volumes. Succeeding volumes will appear at intervals of from two to three months. It is arranged as follows:

Vol. I. Mechanics, Engineering and Heat.
Vol. II. Electricity.
Vol. III. Meteorology, Metrology, and Measuring Apparatus.
Vol. IV. Optics, Sound, and Radiology.
Vol. B. Metallurgy and Aeronautics.

It would be difficult to over-estimate the importance of the dictionary. It is the first attempt which has been made to bring within the compass of a single work the latest results of research, and the most approved methods in all branches of the subject.

It will prove invaluable to all manufacturers who are vitally concerned with the question of physics as applied to industry, which has grown enormously in the past few years.

The experience of the war has enforced more strongly the lessons thus taught, and the importance of Applied Science is now universally admitted.

COAL AND ASH HANDLING EQUIPMENT

(Continued from Page 25)

stoker dumps. These hoppers should be built as large as possible and have at least sufficient capacity to hold several hours run of ashes or the ashes which accumulate during the operating cycle of the boiler room. The best arrangement is to construct these hoppers of steel plate lined with hard burned common red brick. Fire brick linings will not do as they deteriorate rapidly owing to the abrasive action of the clinkers and the extreme temperature variation caused by hot ashes and water used for quenching the same. These hoppers should be equipped with gates of sufficient size to pass the largest clinker which operates easily and quickly. Large size gates should be operated by compressed air or steam so as to insure ease, positiveness and speed of operation. These hoppers discharge by gravity into railroad cars, motor trucks which deliver the ashes to a dump or into a small narrow gauge car which delivers the ashes to a skip hoist which lifts the ashes to an elevator bunker from which they are taken away by trucks or boats.

The car used for conveying the ashes from the hopper to the skip hoist should be of sufficient size to hold all the ashes which will flow out of the hopper at one opening of the gate. It should be especially strong and rugged with provision for replacing the car body as it wears out. This car may run on a truck and be propelled by hand, by gasoline motor, by electricity, taking the current from a trolley wire or storage battery. The hand propelled car is, of course, thoroughly dependable. It is, however, unsuited to large installations. The gasoline motor is a balky machine unsuited to boiler room labor. The trolley wire is a source of trouble due to short circuits and occasionally an employee is electrocuted. The storage battery car has now been developed to the point where it is a reliable machine and easy to operate. Charging of the batteries can be done on a systematic routine by having duplicate batteries. This car may either operate on a track or be equipped with rubber tires and operate without a track. It is an especially flexible arrangement without the track and quite satisfactory in all respects. The car should be opened with a dumping body which may be operated by hand or mechanical means if the body is large.

The skip hoist system is about the only successful one for handling large clinker without first breaking the clinker. The ashes do not come in contact with moisture and the maintenance is, therefore, low. As the investment in the car and skip hoist is comparatively high, it can be used only in plants of large capacity.

Regarding the use of chain and bucket conveyors for handling ashes, the abrasive action of the ashes, the chemical effect of sulphur, and corrosion due to water, causes all mechanical conveyors to wear out rapidly, particularly if the moving parts are in contact with the ashes. Furthermore, such conveyors do not satisfactorily handle clinkers.

It is becoming common practice in very large modern plants to install the boilers on the second floor of the plant with ash hoppers of ample capacity. A railroad track is located on the ground level under the hoppers and the ashes are dropped directly into the cars.

This is the most successful and simplest way for handling ashes in a very large plant. There is sometimes trouble however, in maintaining cars when wanted.

Vacuum and Steam Jet Conveyor System

Ashes may be conveyed through a pipe by passing large volumes of air at high velocity through the pipe. This velocity is obtained by the use of an exhauster at the discharge end of the conveyor pipe or by means of a steam jet blowing into the pipe between the point where the ashes are taken in and the point where they are discharged.

The first is known as the vacuum system and the second as the steam system.

Both of these systems permit conveying horizontally and vertically which has the great advantage of delivering the ashes to an elevated bunker—which in turn can deliver by gravity to a truck or other conveyance.

The conveyor pipe should be as large as is warranted by the boiler horse power or the maximum amount of ashes that will be handled in a given period. Experience has shown that an eight in. pipe is about as large as is practicable to use without requiring an excessive amount of steam or power. It is therefore, obvious that the largest clinker that can be handled must be capable of passing through an eight inch pipe. This type of system is, therefore, adapted particularly to the plant which has few clinkers or clinker of a small size. Hence it is a system which is not widely used with high capacity stoker fired plants of even moderate size. Generally speaking they are suited for hand fired plants of 1,000 horse power or less. The ashes may be conveyed horizontally about 300 ft. and elevated about 100 ft. The maximum capacity of such a system is from 8 to 12 tons of ash per hour.

ISOTHERMAL AND ADIABATIC EXPANSION

(Continued from page 31)

the cylinder wall as efficiently as possible to avoid any heat losses through the walls. That is, we wish to get the curve of expansion as close to the adiabatic curve as possible.

The adiabatic curve will always lie higher than the isothermal curve owing to the exponent due to the ratio of specific heats. Therefore in compressing air or ammonia keeping the curve of compression close to the theoretical or isothermal line, lessens the work to be performed by the motor, while in expanding steam in a cylinder of an engine keeping the curve of the diagram close to the adiabatic theoretical line, makes the area of the diagram bigger, and thus more power is developed per stroke.

The actual expansion or compression curve as described on the indicator diagram always lies between these two theoretical curves and the closeness with which it approaches them gives a measure of the thermal efficiency of the apparatus under examination.

APPRECIATION FROM OTTAWA

Editor, Power House:

Kindly accept the hearty thanks of Ottawa Lodge No. 6 C. A. S. E. for your kindness in providing space in your valuable paper for the publicity of our educational work and meetings during the past year.

Yours Fraternally,
R. E. Rodney,
Rec. Sec.

We have received from the Dayton Dowd, Quincy, Ill., their bulletin, No. 248 which supersedes bulletin No. 245. The bulletin is descriptive of the various lines of centrifugal pumps manufactured by the Dayton Dowd people, a large variety being described and illustrated. A number of typical installations are also illustrated.

MONCRIEFF'S

Moncrieff's "Unific" is not a cheap glass. But because it outlasts many ordinary glasses the "Unific" is economical. British Made.

"UNIFIC" WATER GAUGE

JOHN MONCRIEFF LIMITED
PERTH, SCOTLAND

GLASSES

The "Unific" does not readily corrode. It resists extreme changes of temperature and withstands the highest working steam pressure.

Canadian Representative: W. J. WALL, 134-136 Bleury St., MONTREAL, CANADA

HINTS TO BUYERS

'Bishop's Adamant' Gauge Glasses

Will resist all Steam Pressure and Variations of Temperature.

REFLEX GAUGE GLASSES

Annealed and Hardened for

LOCOMOTIVES, STEAM WAGONS, MARINE AND STATIONARY BOILERS.

Adamite Gauge Glass Rings. Glass Tubes and Rod

S. & C. BISHOP & CO., ST. HELENS, LANCASHIRE.

Kingsbury Thrust Bearings

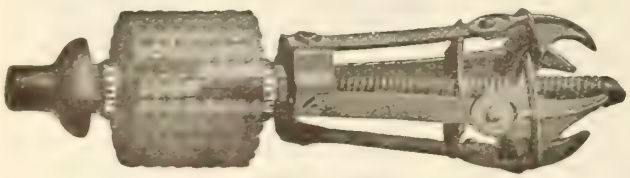
Made in Canada

Our pivoted-block Thrust Bearings are a complete solution of all thrust-bearing problems in hydro-electric units, steam turbines, ships' propeller shafts, centrifugal pumps, and similar work involving heavy loads and high or low speed.

Maximum Durability and Reliability.
Lowest possible Friction.
No limit to loads or speeds.
Protected by numerous Canadian Patents. Complete manufacturing facilities in Canada, insuring prompt deliveries and service.
Send for Catalogue.

Kingsbury Machine Works
Frankford, Philadelphia, Pa.

The Simplest and best cleaner on the market is



PILLEY'S

Combination Flue Brush and Scraper.
Guaranteed not to break or the wires to pull out or lay over. A simple turn of the hand adjusts it to the tube, and the brush removes what the scraper loosens.
For sale by leading Canadian jobbers.
Manufactured by
PILLEY PACKING AND FLUE BRUSH MFG CO.
623 South Third Street - - - St. Louis, Mo
Eastern Office: 71 Fulton St., New York.

"Pop Off" Steam Carries Ashes Away

"Into the hole and away they go" describes ash removal with a Green Steam Jet System. At the Kewanee Boiler Co., they use "Pop off" waste steam to do the work.

Canadian Association *of* Stationary Engineers

Incorporated May, 1887
In orporated at Ottawa June, 1917

This Organization is founded on the following principles

—The better education of its members in the science of steam engineering.
—To protect the competent engineer and his vocation.
—To enroll all competent engineers in this organization.
—To impart information beneficial to the profession.
—To assist members out of employment to obtain the same.
—To procure by legal enactment greater safety in the operation of steam plants.
—The belief that knowledge and ability of one's profession is what is necessary to make success possible.

Brother Engineer:

Did it ever appeal to you to join an association devoted entirely to the interests of the engineering profession; one which by means of lectures, illustrated and otherwise, delivered in the lodge room, tends to keep its members right up to the minute with the progress made in the engineering professions?

If you are interested in an association of this kind, and live where less than fifteen engineers reside, send for a copy of our constitution, and make application to the nearest lodge for membership. If you live where more than fifteen engineers live, get together and send in a written application to me.

The undersigned will be very pleased to give any further information required.

F. HARPER, President Grand Lodge.
89 Bay Street, Kingston.

L. J. ELLIS, Sec.-Treasurer Grand Lodge.
142 East Avenue, N. Hamilton.

CYCLONE GRATES

The Canadian Steam Boiler Equipment Co., Limited

Sole Makers for Canada

20 McGee Street Phone G. 3660 Toronto, Ont.

AGENTS:
ST. JOHN, N.B.; F. W. Blizard, 329 Charlotte St. MONTREAL: Mason Regulator Co., Ltd., St. James St. HAMILTON: Robt. Fitzsimmons, 8 Grove St WINNIPEG: Vulcan Iron Works. OTTAWA: Campbell Steel & Iron Works, 855 Carling Ave.

These shaking and dumping grates are saving tons of fuel annually in Canadian plants—we will be pleased to supply names of users. Remember, what Cyclone Grates are doing for others, they will do for you.

POWER HOUSE BUYERS' DIRECTORY

If what you want is not listed here write us, and we will tell you where to get it. Let us suggest that you consult also the advertisers' index facing the inside back cover, after having secured advertisers' names from this directory. The information you desire may be found in the advertising pages. This department is maintained for the benefit and convenience of our readers. The insertion of our advertisers' names under proper headings is gladly undertaken, but does not become part of an advertising contract. Readers are requested to advise the publishers regarding any equipment that they are buying and that is not listed.

Power Plant Equipment

New or Rebuilt

Whether it be new or rebuilt you may always be sure of getting dependable equipment when doing business with Petrie.

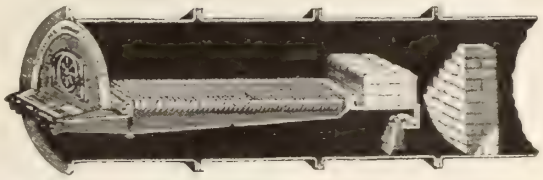
Apart from price considerations you will find the Petrie Service mighty useful. Whenever you need them, our experts are ready to serve you—promptly, intelligently and willingly.

You'll be well-advised to look over our lines of Vertical, Horizontal and Firebox Boilers; Marine, Automatic, Vertical and Horizontal Engines, etc.

H. W. PETRIE, LIMITED

Toronto and Hamilton

The TURBINE Furnace



Eats Up Everything But High Fuel Costs

Coal slack—coke dust—cheap low grade fuel —everything is the same to this furnace which represents the highest form of fuel economy.

As a test, P. Burns & Co., of Vancouver, accomplished 7 lbs. of steam per lb. of coke dust at 212° F.—Others were equally satisfied. Stop burning expensive fuel—let the Turbine Furnace save you money.

Manufactured by the Turbine Furnace Co., Limited, London, England.

Sole Canadian Agent:

PERCY A. GOEPEL

525 Pender Street West, Vancouver

BETSON'S

REG. U.S. TRADE MARK PAT. OFF.

PLASTIC FIRE BRICK

ELIMINATE LOOSE BRICK *and* FALLEN ARCHES

by using BETSON PLASTIC FIRE BRICK for repairs and for building complete, seamless, monolithic furnace linings, including front and rear arches, side walls, bridge wall and baffles.

No more fallen arches—no more in-leakage of cold air. But more power with less expense.

Shipped either mixed ready for use or dry to mix with water (the cost is the same) from our storehouses in principal cities.

Write for valuable booklet.

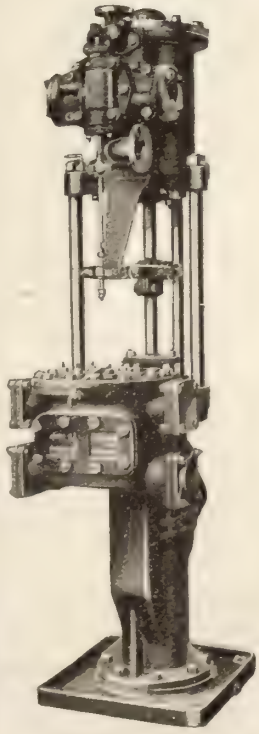
Save the Engineer's Time



Use the

HEPBURN "Special"

SIMPLICITY dominates the construction of this "Special." It has only one packing gland to need attention and no bucket rings to change; no loose parts to need attention and no adjustments are necessary.

Designed for high steam pressure and for water of high temperature, it has a reputation for maximum efficiency on minimum upkeep charges. It is equally satisfactory for both marine and land service.

Write for Catalogue.

Our Men KNOW

They go right into a customer's fire box to learn what's wrong. Then they show him how to remedy it with

PLIBRICO JOINTLESS FURNACE LINING

PLIBRICO settings will make any boiler produce more steam at less fuel cost. Its smooth, **jointless** walls are air tight and gas tight, they resist heat up to 3,100° F., and outlast ordinary fire brick many times.

Send for our catalogue, K-62, on "Modern Furnace Building," or **Ask The Plibrico Man—He Knows. PLIBRICO is delivered only in steel containers of distinctive appearance as shown below.**

DISTRIBUTORS—Beveridge Supply Co., Ltd., Montreal, Que.; Shell Bar Boico Supply Co., Ltd., Toronto, Ont.; Evans, Coleman & Evans, Vancouver, B.C.; Winnipeg Supply & Fuel Co., Winnipeg, Man.; Gorman's Ltd., Calgary, Alta.

1142 CLAY ST., CHICAGO, ILL.

SPECIAL NOTICE TO SUBSCRIBERS

We have received some complaints from subscribers to the effect that Power House is not being delivered. In almost every case investigation has shown that our friends have changed their addresses and have NOT notified us.

Let every subscriber look at the address on the label on this issue of Power House, and if it is not correct, please fill in and mail to us the following—

Address "Power House"
143 University Ave. Toronto, Ont.

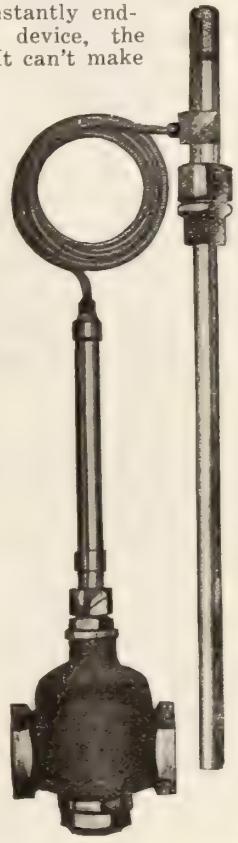
DON'T GAMBLE with Temperatures!

In many manufacturing processes which call for the use of liquid solutions at given temperatures, it is sheer gambling to depend upon the uncertain "human element."

Sooner or later the man who is "infallible" proves that he is *not infallible.* And then—he takes his hat and coat off the peg and walks out of your plant with a pink slip in his envelope.

But does that save your goods? And does it save your good name? How many times in the past have inferior goods gone out to undermine your reputation?

All doubt in this connection is instantly ended by the reliable, sure-control device, the Sarco Temperature Regulator. It can't make mistakes. It can't go wrong. Once set for a given temperature it maintains that temperature faithfully. It gives you the positive assurance that your solutions are neither too hot nor too cold—that your goods will not be ruined in process of manufacture, day or *night.*



Simplicity is the keynote in the construction of this instrument. The prime agent in the control of heat-volume is an expansion-and-contraction element controlled by a super-sensitive liquid. There are no outside devices to invite break-down and expensive repair. No electricity, water or compressed air. The Sarco is entirely self-contained. Compact — small in size — durable. And lower in price than any other temperature regulator.

Sold on 30 days' free trial.
For full particulars write for Booklet No. J-67.

For Self-Promotion And Sales Promotion

Are you interested in any of these fields—power—metal working —marine? As a manufacturer, or purchasing agent, as a superintendent or foreman, as an ambitious mechanic or engineer?

Use These Publications

They will keep you strictly up-to-date in all branches of mechanical engineering. Edited by practical men. Cheerful, inviting, instructive, authoritative.

POWER HOUSE

Twice a month—$2.00 per year.
Serves the power plant engineer—Steam, Electric, Refrigeration, Hydraulic.

CANADIAN MACHINERY

Weekly—$4.00 per year.
Covers the metal working field—serving shop executives, purchasing agents and owners. First-class mechanical paper and market paper combined.

CANADIAN FOUNDRYMAN

Monthly—$2.00 per year.
A paper for the foundry owner, superintendent and foreman. Claimed by its readers to be unexcelled.

MARINE ENGINEERING

Monthly—$2.00 per year.
Interprets marine engineering in its broadest sense, serving the shipbuilders, navigation companies and their officers. (The editor holds an extra first-class B.O.T. certificate.)

Published by

THE MACLEAN PUBLISHING CO., LIMITED

143-153 UNIVERSITY AVE., TORONTO

A company whose idea of service has made it the largest concern of its kind in the British Empire.
Thirty years' experience and dozens of practical men in your own line, stand ready to serve you. Let them! Subscribe for your paper to-day.

Men with selling problems will find a profitable tip in the statement made by a prominent manufacturer recently, "I use MacLean Publications because I am satisfied that papers with such a high standard of editorial excellence, MUST have an influential following."

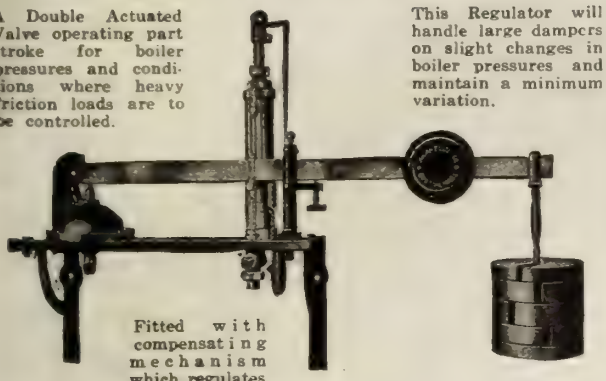
D'ESTE

Hydraulic Damper Regulator

A Double Actuated Valve operating part stroke for boiler pressures and conditions where heavy friction loads are to be controlled.

This Regulator will handle large dampers on slight changes in boiler pressures and maintain a minimum variation.



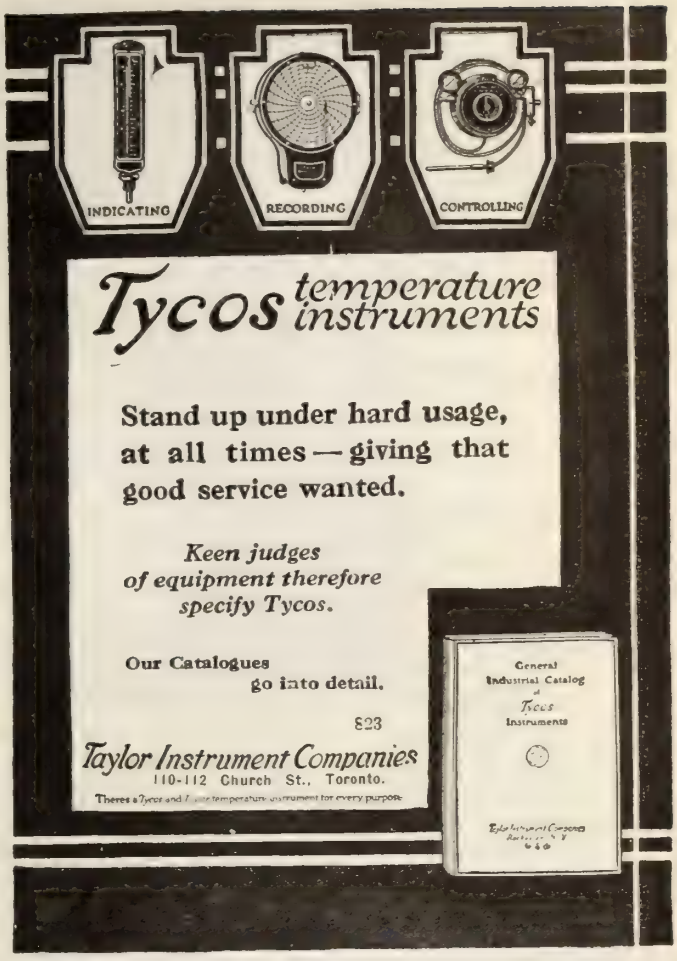
Fitted with compensating mechanism which regulates opening and closing.

Our Catalogue No. 50 of CURTIS ENGINEERING SPECIALTIES sent on application.

Julian d'Este Company

Main Office: 26 Canal St., Boston 14, Mass.

Agencies:
318 W. Washington St., Chicago.
180 Washington St., New York.



INDICATING
RECORDING
CONTROLLING
Tycos temperature instruments
Stand up under hard usage, at all times—giving that good service wanted.
Keen judges of equipment therefore specify Tycos.
Our Catalogues go into detail.

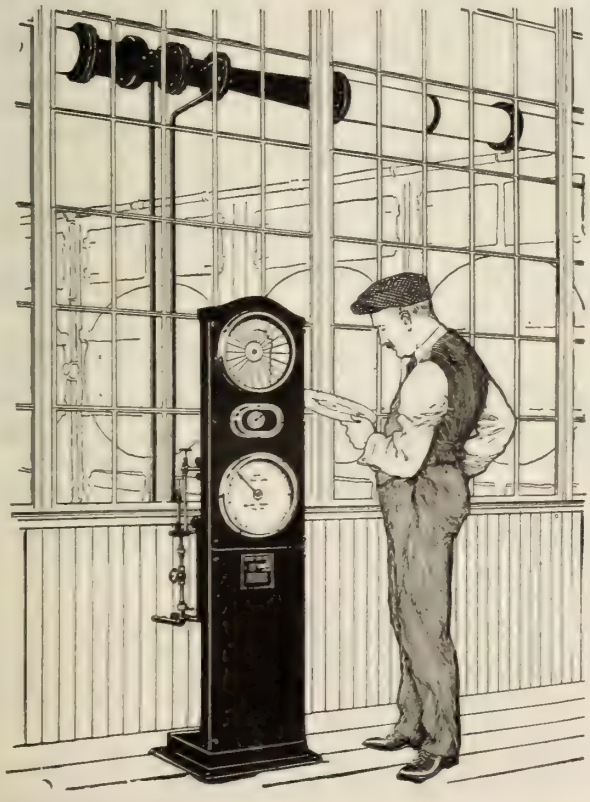
Taylor Instrument Companies
110-112 Church St., Toronto.
General Industrial Catalog of Tycos Instruments



Constant Knowledge of Boiler Plant Results

The Chief Engineer who insists on maintained efficiency in his plant, must have proof of such a condition. For the story of his boiler plant, he has only to study the charts from the

VENTURI
Boiler Feed Meter

Over twenty years of service has proved the Venturi to be supreme for boiler feed measurement. It is accurate, durable and needs little attention; it gives the momentary rate, total flow and a 12 in. chart record of each 24 hour period. It has long been accepted as the *standard meter* for the boiler room.

A Section of a Return Bend used in

ELESCO

SUPERHEATERS

Send for Bulletin NT-2

THE IMPORTANCE of the Return Bend in Superheater Design

ELESCO forged return bends used in ELESCO Superheater designs are made on the ends of the units from the metal of the pipe itself by a special mechanical forging process, without the use of electrical or acetylene welding and without the addition of any material or metal.

This construction provides a continuous pipe and greatly reduces the number of joints to be maintained steam tight.

A sharp return, thoroughly mixing the steam, is provided, without adding excessive pipe friction.

The ELESCO forged return bend facilitates the advantageous location of the units and offers a minimum obstruction to the passage of the gases.

Where provision for interior cleaning is desired, the ELESCO return bend is advantageous because its construction allows the cleaning tool to reach the bend and thoroughly clean it.

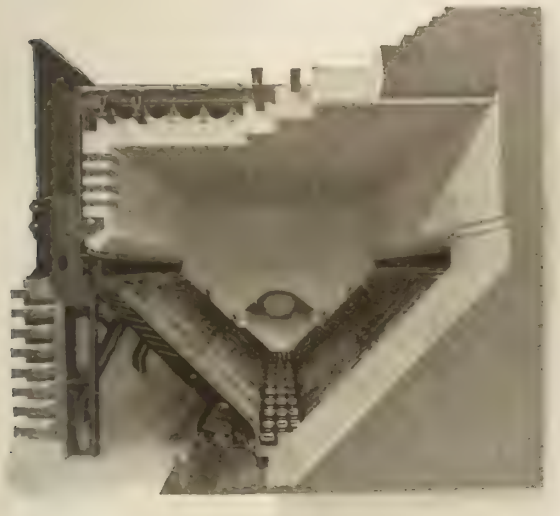
DETROIT "V" TYPE STOKERS



Detroit "V" Type Stoker, Heavy Duty Type, with Detrick Flat Suspended Arch (rear view)

Quartersection, Radial Straight Arch Stoker, showing Coal Magazine and arch support, with removable tuyeres and protecting brick

The special Fire Brick shapes furnished with Detroit Stokers are made from the highest quality refractory material, molded by hand in steel molds and repressed to insure uniformity and durability.

Secure Complete Combustion

You have gone to large expense in installing up-to-date equipment in your plant, to insure economy in operation. How much of the potential energy in your fuel are you actually utilizing in producing steam?

Very much less than you could or should if your boilers are hand fired!

Compare some of the advantages of Detroit "V" Type Stokers over uneconomical hand firing!

A. Hand firing is intermittent, its evenness and effectiveness depending upon the individual skill and attentiveness of the fireman. With Detroit "V" Type Stokers the human factor is eliminated; firing is continuous and uniformly even, assuring high combustion efficiency.

B. With hand firing, one fireman can at the best take care of 250 to 500 H. P. of boilers, whereas with Detroit Stokers the same man can handle 2000 to 3000 H. P. thus reducing labor costs 75 per cent.

C. Detroit "V" Type Stokers burn cheaper grades of fuel than can be used to advantage with hand firing, thus paying for their cost several times over each year.

In addition consider the advantages of control of air admission, thorough automatic cleaning of fires, and smokeless operation, resulting from a Detroit Stoker installation.

Detroit Stokers today represent the best fruits of a practical knowledge gained in the Company's twenty years of successful stoker building, and the recent important developments in the science of combustion. There is a type for every purpose—"V" Type overfeed for natural draft—Single Retort Underfeed for boilers developing up to 300 to 400 H. P.—Multiple Retort Underfeed for large installations.

Take the first step toward reducing boiler room costs. Write for full information.

STEAM GOODS

"Every Installation a Demonstration of Merit"

The Value of a Standard Line

GOODS of any kind that have been on the market for a long time and have established a reliable reputation for quality may be said to be "standard." That is, buyers instinctively accept the goods without question. A case in point is seen in respect to Morrison's Steam Goods. Every competent engineer knows that if an article is of Morrison design and manufacture it will give the utmost service. There is never any reason to question the wisdom of buying Morrison-made equipment.

Some of Morrison's Steam Goods:

Stop and Check Valves.
Safety and Relief Valves.
Reducing Valves.
Steam Traps, Injectors.
Ejectors, Inspirators.
Jet Pumps.
Pressure Gauges.
Pipe, Tools, etc.
Gauge Board Outfits.
Lubricators.
Pipe and Fittings.

MONTREAL, WINNIPEG, VANCOUVER LONDON, ENG.: 88 Fleet Street, E.C. NEW YORK, BOSTON, CHICAGO

Vol. XV.—No. 11 Publication Office, Toronto—June 5, 1922 Published Semi-Monthly Canada, $2; U.S. $2.50 a year

Showing General Scheme of Manitoba Power Company's Development

The Great Falls Power Development on the Winnipeg River.

The construction work now being proceeded with at Great Falls, by the Manitoba Power Company, Limited, signalizes the beginning of the principal link in a chain of potential developments extending from Lake of the Woods to Hudson's Bay, and aggregating several millions of horsepower.

Concrete will, of course, play an important part in the entire project. The dam, on the west shore to the power house, 750 feet long and with maximum depth of 75 feet, will be of the usual solid concrete non-overflow type.

The power house will be 110 feet wide, 380 feet long, and will have a maximum height of 145 feet. The foundations will be of reinforced Concrete.

The design of the plant is modern in every respect, and in physical dimensions and quantity of water used, the turbines are the largest ever installed.

Sir Augustus Nanton is president of the Manitoba Power Company, and Mr. A. W. McLimont, vice-president and general manager.

Mr. Julian C. Smith is supervising engineer; Messrs. L. J. Hirt, R. S. Lea and C. O. Lenz are consulting engineers. Mr. F. H. Martin is chief engineer and designer.

The contractors are Fraser-Brace, Limited.

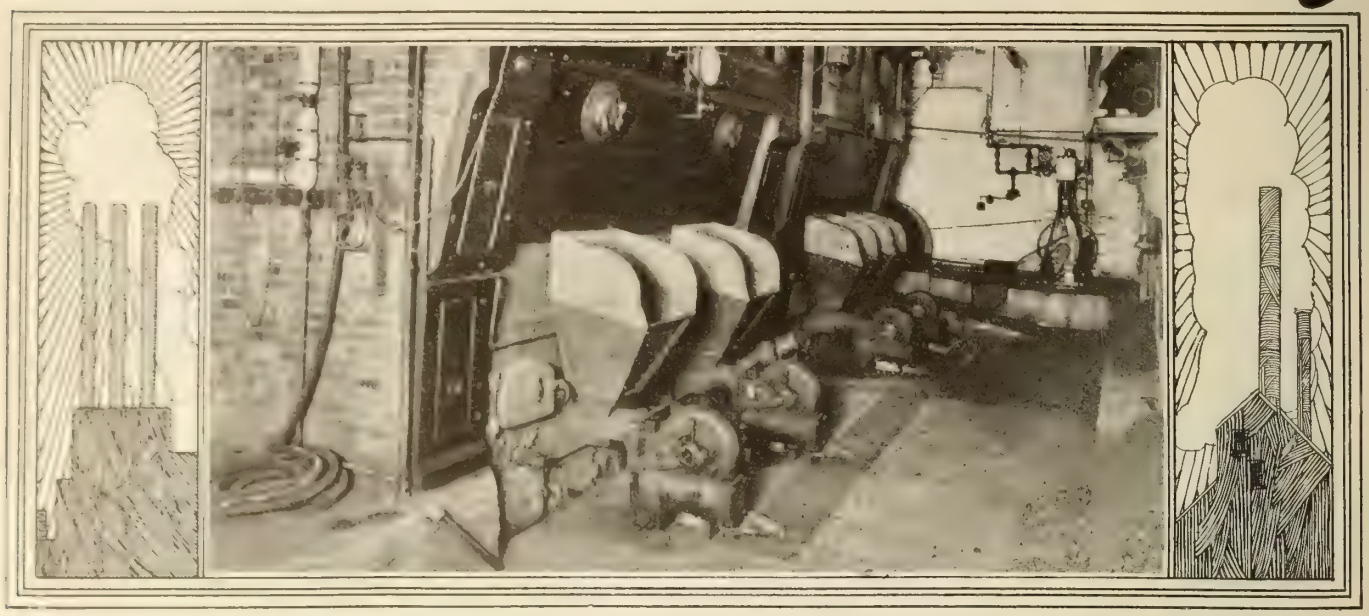
Detroit Single Retort Stokers Effect Remarkable Fuel Saving



THE Detroit Single Retort Underfeed Stokers illustrated above, are installed in the power plant of a prominent Cincinnati shoe manufacturing company.

This power plant, containing water tube boilers and another type of stokers, had been operated for a number of years by a very efficient force, who, in five years, succeeded in reducing the fuel consumption from approximately 12 tons per 10 hour day to 10 tons per 10 hour day under the same load conditions.

Two years ago the old equipment was discarded, and water tube boilers of the same make installed. These were equipped with the Detroit Single Retort Underfeed Stokers shown.

This installation is in daily operation and the fuel consumption has now been reduced to 6 tons per day. A saving of 40% in fuel has thus been secured.

Uniform steam pressure is now maintained and recent tests under every-day operating conditions show an overall efficiency of boiler and stoker better than 75%.

Similar savings may be possible in your plant. Let us investigate your conditions and submit recommendations.

In addition to the Single Retort machine we manufacture V-Type Stokers for natural draft, and Multiple Retort Underfeed Stokers for large boilers. Write for full information outlining your boiler conditions.

Files Hand Stokers Getting Results

PANTHER RUBBER COMPANY, LIMITED

GENERAL OFFICES AND FACTORIES
SHERBROOKE, QUE.

Rec'd Sept. 26/21.

SHERBROOKE, CANADA September 23, 1921.

The Waterous Engine Works Co. Ltd.,
Brantford, Ont.

Gentlemen:

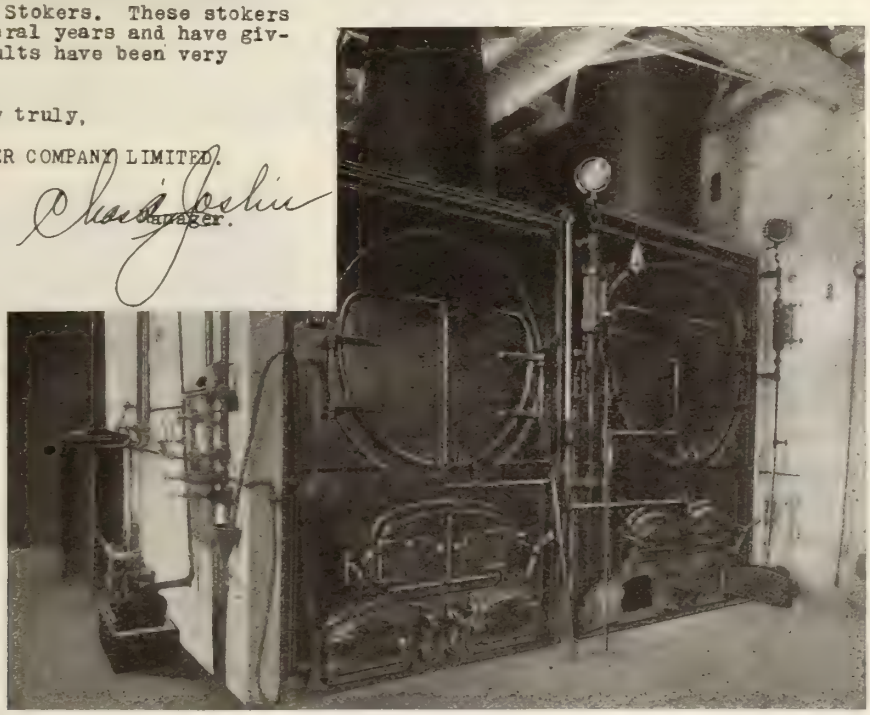
In reply to your letter of the 8th instant we have in our plant the Files Stokers. These stokers have been in operation for several years and have given excellent service. The results have been very satisfactory.

Yours very truly,

PANTHER RUBBER COMPANY LIMITED.

Manager.

CAJ/RMK



It is the uniform excellent service and general satisfaction that have caused progressive men to select **Files Stokers.** These are typical of the more complete data we have compiled:

One installation (3,600 H.P.) saved enough coal to pay for their stoker investment in five months.

A Files installation operated for five months continuously at an average rating of 223%—doubling their steam output.

Files stokers increased efficiency of one plant sufficiently high to warrant discontinuance of two out of eight boilers.

Here is a ready explanation of these achievements:—

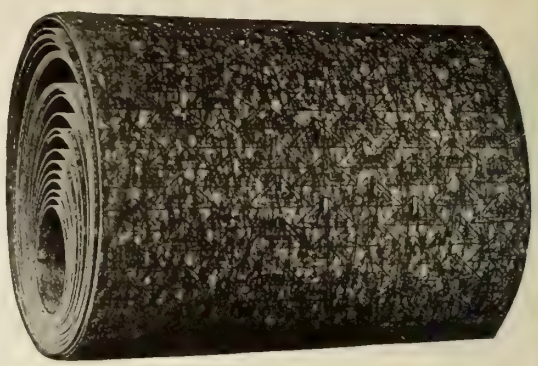
1. **Complete volatilization of green coal, causing intensified combustion and smoke dissemination.**
2. **Correct distribution and proper proportion of air according to load carried.**
3. **Fuel bed continuously kept clean, uniform and rich.**

Given the opportunity we will be glad to present these facts for your complete satisfaction.

The Waterous Engine Works Company, Ltd.

Brantford, Ontario

For Tight Joints



Durabla compressed asbestos fibre sheet packing makes tight joints on steam, water, air, oil, ammonia and acids at all temperatures and pressures. Joints can be broken without injury to gaskets. It will not burn out, blow out, pulp at the joints; requires no following up and is not affected by vibration or condensation. Durabla Packing meets all conditions of shipping and storage.

"P.M.S" BELTING

Try it! Test it! Compare it!

We court investigation. "P.M.S" Belting is recommended, and sold strictly on its merits—of course; it's well-made of exceptional materials. The toughest of Sea Island Cotton, rubber-friction-surfaced to make it non-slip and assure the maximum transmission of power, is the basis of "P.M.S" excellence. But, to convince yourself, just try it! Test it! Compare it with others! Give it the severest trial you like, so long as it's a fair one. Then, you'll appreciate "P.M.S", as we know it—practically perfect belting.

TRADE MARK

New Truths and Old Fallacies

A PARTING SHOT

Now, in conclusion, please excuse us for paying our respects to certain competitors whose shibboleth is "just as good," or "the same thing" as Magnolia.

Admit, if you please, for the sake of argument, that they know, at least, the approximate formula of Magnolia—then what? Does an analysis show our foundry practice and thermal treatment? Does it show our graphite treatment? Have most of these people ever heard of impurities of low atomic volume, or have they the remotest idea as to what an eutectic is, as applied to babbitts?

Their literature, that we have seen, denotes their entire ignorance of these subjects, and never, by any chance, give comparative figures of tests, with and without lubrication, or have anything to say regarding co-efficients of friction. Apparently the extent of their information is confined to a knowledge of the formulas of the general run of "commercial babbitts," and the finer points of compounding are evidently not dreamt of in their philosophy.

Some of them will make any claim and quote any price to obtain business, without regard to the interest of their customers, and this is often done by well-meaning people who are uninformed on the subject.

No other concern than Magnolia Metal Company has ever given out so much useful information regarding babbitt metals. When it comes to the cold analysis of figures and facts, is not the discreet silence of other concerns a fair inference that they have nothing of equal value to report?

We lay our cards on the table face up, and ask that our competitors be at least required to do the same thing.

It never pays to buy the cheaper grades of anything, as a dime saved in price is often a hundred dollars lost in efficiency.

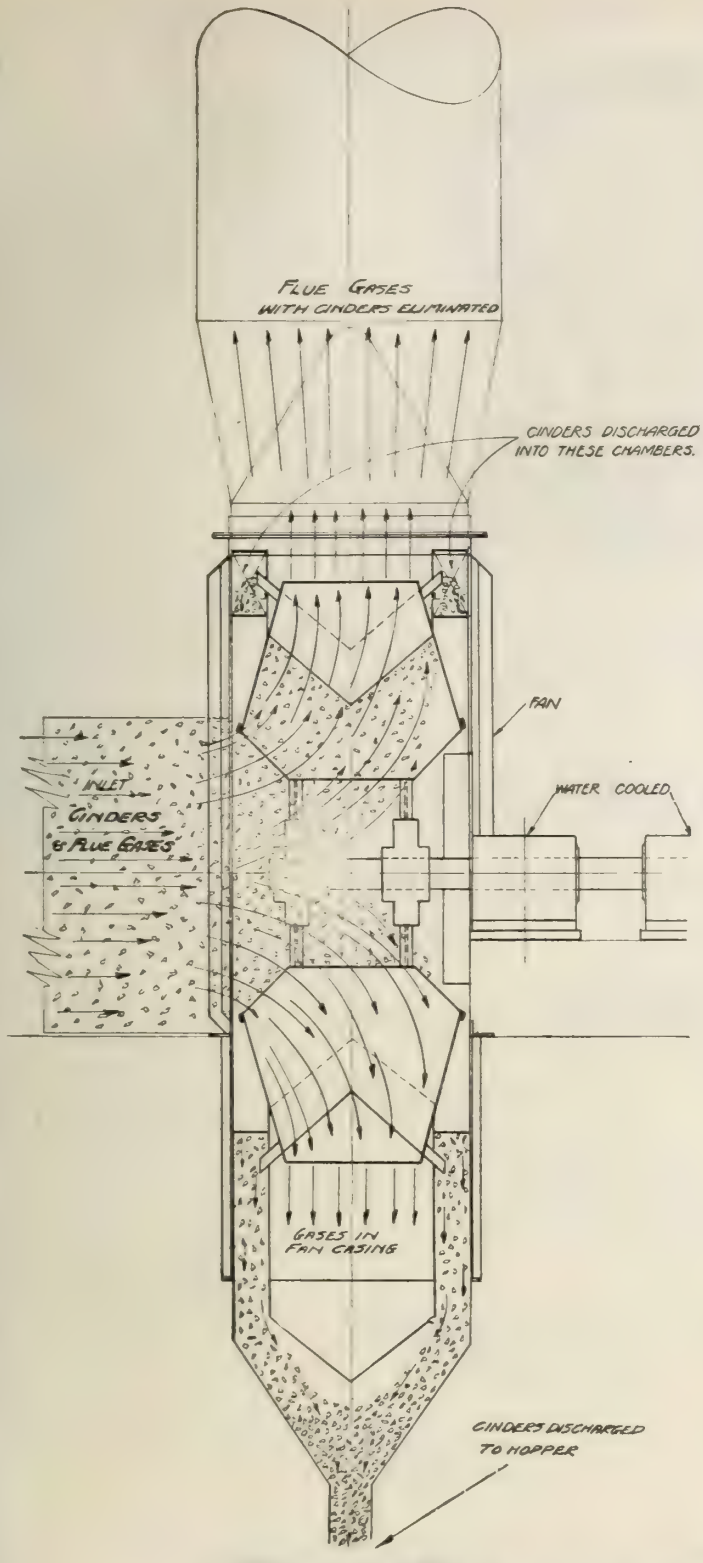
LEONARD



This is how the Cinder Eliminating Induced Draft Fan Works

The fan casing is directly connected with the flue. Everything that gets into the flue—fine or coarse material, gases—everything, must first go through the fan. There are a series of guiding vanes running across each of the fan blades which lead the solid material to the inclined channels on each fan blade. The solid material runs into these channels and is then thrown out by centrifugal force into a "dead" space between the fan and the casing; this solid matter falls into a hopper and can be conveyed where desired, while the gases only go up the stack.

The revolving fan at the same time furnishes a most efficient induced draft.

Two hundred and fifty pounds of solid matter an hour was collected by each fan in one New York plant.

The Importance of Keeping the Bearing Surface of a Rod Well Lubricated

Most packings contain little or no lubricant, and present a friction producing surface to the rod, which wears a hollow in rod where it passes through the stuffing box, and quickly destroys the packing itself.

TRADE MARK
"PALMETTO"
REG U S PAT OFFICE

has lubricant forced into each single strand under pressure before braiding. This lubricant works to the rod and keeps the bearing surface covered with a film of graphite grease, reducing friction to the lowest point.

The perfect lubrication of "Palmetto" packing prevents the wear of rods, and is one of the reasons why "Palmetto" gives Longer service than other packings.

Let us send working samples of braided and twist "Palmetto" so you may understand the value of a perfectly lubricated packing.

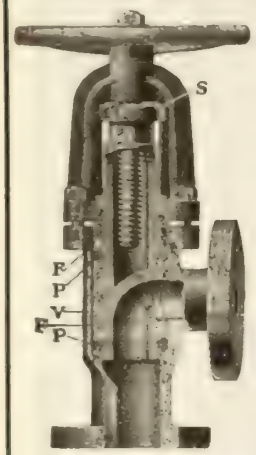
No Seat to Leak—

the Outstanding Reason for the Success of the

YARWAY

Seatless Blow-Off Valve

(Formerly the Simplex)



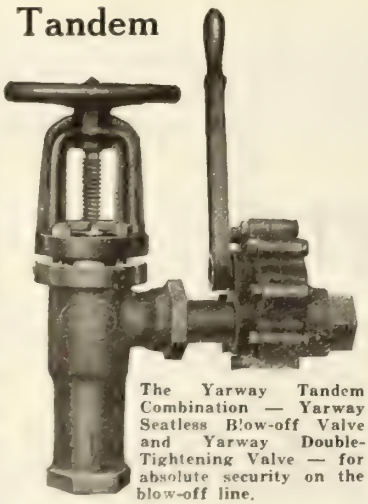
After the YARWAY SEATLESS BLOW-OFF VALVE has closed, shoulder S on plunger V engages the loose follower gland F. A hard turn of hand wheel then compresses packing P above and below the port, making an absolutely tight valve.

No blow-off valve seat has yet been made that can successfully withstand the cutting, scoring, destructive action of grit and sediment forced against it under high pressure. Consequently, the ordinary blow-off valve is a source of constant trouble and expense.

Because the Yarway Seatless Blow-off Valve eliminates this most troublesome part—because it stands up in service for years without repairs—because, being a slow-opening valve, it precludes all possibility of water hammer and ruptured blow-off piping—and because it is carefully made of sturdy material, it has won success in hundreds of well-equipped plants in this and other countries.

The Yarway Tandem

The combination of a slow opening plunger valve which can be depended upon to keep the line tight and prevent water hammer, and a quick opening lever operated valve for use in case of emergency or repair, has gained widespread favor recently. For such service the Yarway Tandem Combination has proved particularly successful.



The Yarway Tandem Combination — Yarway Seatless Blow-off Valve and Yarway Double-Tightening Valve — for absolute security on the blow-off line.

The stoker that keeps everlastingly at it

BY KEEPING everlastingly at it in hundreds of plants, Jones "A-C" Stokers have won nation-wide success.

The Jones "A-C" never fails to give a day's work—and that means a 24 hour day if the plant load requires it. This high-duty stoker is so simple in design and so rugged in construction, that it easily stands the punishment of heavy, prolonged overloads and peak loads ranging to 300 per cent. of rating and over.

Simplicity—and the staying power that goes with simplicity—is gained without a sacrifice in combustion efficiency. For simplicity is an inherent advantage of the correct application of the under-feed principle of combustion—the principle that was first introduced in the Jones Stoker.

Thoroughly, but not too technically, the new book "Ten Points of Jones Superiority," explains the advantages of the Jones "A-C" Stoker in a way that will interest any Canadian plant operator. When shall we send your copy?

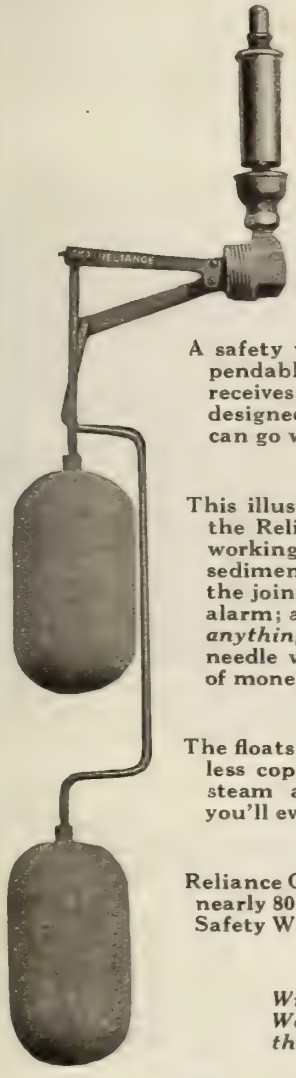
positive warning that the water in your boilers has reached a dangerous level



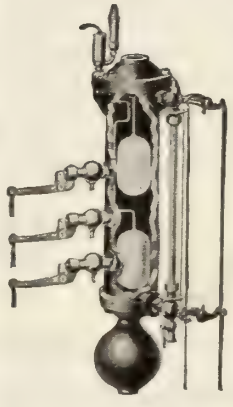
A safety water column must be absolutely dependable—*ALL* the time. Even though it receives only perfunctory care, it must be so designed and built that practically nothing can go wrong with it.

This illustration shows the vital mechanism of the Reliance high and low water alarm. All working parts are up out of the water; no sediment or foreign deposits can clog or stiffen the joints. There is a separate float for each alarm; and the low alarm float is so set that if *anything* happens to it the whistle blows. The needle valve which the levers operate is made of monel metal—you know what that means.

The floats are Reliance made of reinforced seamless copper, and every one factory tested to steam and water pressures far higher than you'll ever subject them.

Reliance Columns *are* dependable. The fact that nearly 80% of all the columns in use are Reliance Safety Water Columns is considerable evidence.

Write to us for full information. We are preparing a new catalog that will be ready soon.



Here is the complete column cut away to show the float mechanism. The cost of this safety device is so low and its service so important, that no boiler plant — one boiler or fifty—can afford to be without it.

Why *Brick* Insulation
at
Provincial Paper Mills

FOR the simple reason that only in brick form can insulation be permanently built into boiler settings. Loose fillings lack structural strength and stability. The insulation to be efficient, permanent and economical, should be an integral part of the construction.

Nonpareil Insulating Brick
For Boiler Settings, Furnaces and Ovens

are made in standard fire brick shapes and sizes. They bond with the refractory and common brick to form a solid wall. The insulation is built in. It cannot settle or break away. It is not affected by jars or vibrations or by the strains of expansion and contraction. It is permanent insulation. And it is economical insulation for the Nonpareil Brick simply take the place of an equal number of common brick and their use does not call for additional construction or for skilled labor.

As for efficiency, a 4½-inch course of Nonpareil Brick reduces by about two-thirds the heat loss by conduction and radiation from walls and arches. The saving in fuel, the greater uniformity of temperature and the more comfortable working conditions in the boiler room, repay the cost of insulation in a year or less.

The uses and advantages of insulation in brick form are explained in the 72-page book, "Nonpareil Insulating Brick," which is sent free on request. Write for it.

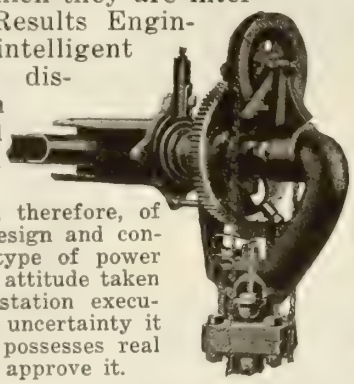
Diamond Valv-in Head Soot Blowers Save Fuel Labor and Steam in the Big Central Stations

AS a group the most critical buyers of power plant equipment are the big central stations. They have every facility for measuring the exact performance of the machines in which they are interested, and their Results Engineers are keen, intelligent judges, quick to discriminate between real and fancied efficiency and economy.



One of the real tests, therefore, of any improvement in design and construction of a given type of power plant equipment is the attitude taken toward it by central station executives. If there is any uncertainty it is not taken up—if it possesses real merit they are glad to approve it.

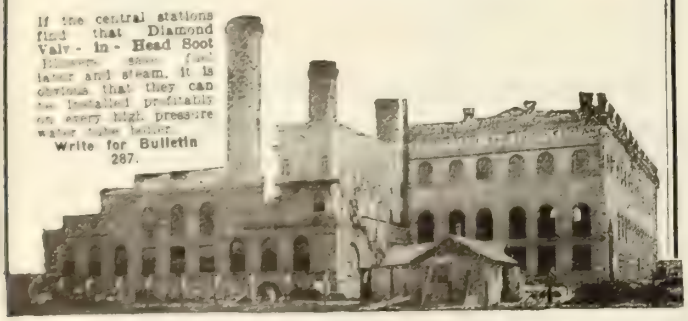
We do not know of any piece of power plant equipment which has ever received from central station executives in the same length of time the cordial welcome and hearty endorsement which has been accorded Diamond Valv-in-Head Soot Blowers.

Over 2,000 units of this new type of soot blower have been purchased by over 125 central stations within the past eight months. Such representative operating companies as Commonwealth Edison, Detroit Edison and Pennsylvania Power and Light have ordered from 126 to 176 units.

You know these Central Station Users of Diamond Valv-in-Head Soot Blowers.

Central Illinois Public Service Company
Duquesne Light Company
Erie County Electric Company
Indianapolis Light and Heat Company
Illinois Traction System
Northern States Power Company
Southern California Edison Company
St. Paul Gas Light Company
United Illuminating Company

(Also see mention of the article on Provincia iamond Valv-in-Head Soot Blowers in Paper Mills in this issue of Power House.)



If the central stations find that Diamond Valv-in-Head Soot Blowers save fuel, labor and steam, it is obvious that they can be installed profitably on every high pressure water tube boiler.

A TYPE FOR EVERY PURPOSE

And Service 'way beyond the average!

Be it a small size water or oil line, or the large size high pressure and high temperature steam line, there is a Lunkenheimer Valve especially suited to the purpose. Every type is designed to give maximum service under extreme operating conditions, and with the line complete, standardization throughout the plant, with its many advantages, is easily accomplished.

With seating surfaces regrindable and all parts made to gauge and renewable, the installation of Lunkenheimer Valves means permanence in the line with a minimum expense for maintenance and repairs.

Our catalog No. 58-DC illustrates and describes the various types in detail. A copy will be sent on request. If you have a valve problem, we will help you—no obligation.

Coal is the least that a leaky steam trap wastes

By the time power gets up to your coils or machines as steam, it costs far more than at the coal pile, heat unit for heat unit. All along the line you are adding charges of firing, oiling, superintendence and overhead.

So to measure the loss from a leaky steam trap in tons of coal or units of power is not enough. This is a fact which drives home the importance of a steam trap worthy of the name.

"Just a ball—that's all!" A floating ball is the only moving part of the Johns-Manville Steam Trap. No valves, levers or thermostats to get out of order. And the action of this Trap, in preventing loss of steam and discharging air and water, is as sure as it is simple.

Why Johns-Manville Steam Traps do not leak

There is always, in a Johns-Manville Trap, a thin water seal between the steam and the outlet. Here is how this Trap works—and the extreme simplicity of its construction means that it always *does* work.

A hollow ball is the only moving part.

When the entering water raises the ball, the discharge orifice is exposed, and water and air flow out.

When the water level drops, the ball drops. It rolls over the discharge orifice, thus throttling down the outflow and maintaining sufficient water in the Trap to prevent steam leakage.

This action is sure. You can depend on the Johns-Manville Steam Trap to save power and so to help cut your operating costs.

The Provincial Paper Mills Power Plant

There Are 750 Rated Boiler Horse Power Installed so Far, and Future Developments Will be Cared for by Extending the Building. The Boiler Room and Its Appurtenances Are of An Interesting Character

By T. H. FENNER

THE LITTLE town of Mille Roches, Ont., has for the reason of its existence the paper mill of the Provincial Paper Co. and in order to maintain production at a normal rate, with moderate production costs, this mill has been furnished with a modern and complete steam power plant, to take the place of the original installation, which has done duty for a number of years.

The new plant is a fine example of design and workmanship, and was constructed to the plans and specifications of Mr. R. S. Kelsch, consulting engineer of Montreal.

The plant has been built with a view to further extension at some future date, and is so arranged that when this development occurs, the present plant will be a complete unit on one side of the stack, and the new unit will be sustained on the other, making a completely symmetrical arrangement. The fans, pumps, etc., are placed in the present boiler room about opposite the stack, so that when the plant is extended, these important units will occupy a central position. The overhead coal bunker, coal receiving grating, coal crusher, elevator and ash bunker, are also situated at one end of the present installation, so that in the future they will also be in the exact centre of the plant.

The Boiler Room

The boiler room consists of a brick building, one story with a basement, the roof being flat, and furnished with a monitor skylight, to carry off the radiated heat from the top of the boilers. In the basement, which is built entirely of concrete, are situated the outlets from the boiler ash pits, and in a separate enclosed apartment extending in front of the building, the coal crusher and coal elevator. In another entirely enclosed apartment in the basement, are the fan engines and the fan, the countershaft which drives the timing arrangement of the stokers being brought through the concrete wall to a position directly under the stokers, and a belt passes through the floor from each stoker timer to the countershaft.

On the boiler room floor are store rooms and wash rooms for the firemen, while directly in front of the base of the stack, is a further concrete totally enclosed room, which contains the feed pumps and heater. The arrangement is such that there is an almost entire absence of dust, even when the coal crusher and elevator is working, and the main boiler room and firing floor present an appearance of spaciousness which is somewhat surprising after observing the building from the outside.

The Boilers

The boilers at present installed consist of three Goldie & McCulloch water tube boilers of the usual longitudinal drum type. The drums are 54 inches in diameter, by 23 feet in length. Each boiler contains 2,636 square feet of heating surface, being rated at 250 horse power. Two of the units are arranged side by side, to form a battery and there is a space between them and the single boiler, permitting room for a passage between in which are arranged the smoke blower connections. Each drum is fitted with the usual combined feed stop and check valve, and two direct connected gauge glasses are fitted to the front of each drum. The blow-off valves from the mud drums are the "Yarway" type, made by the Yarnall Waring Co. and from the outlet of the valves pipes are led down into the basement and from there to a blow-off tank

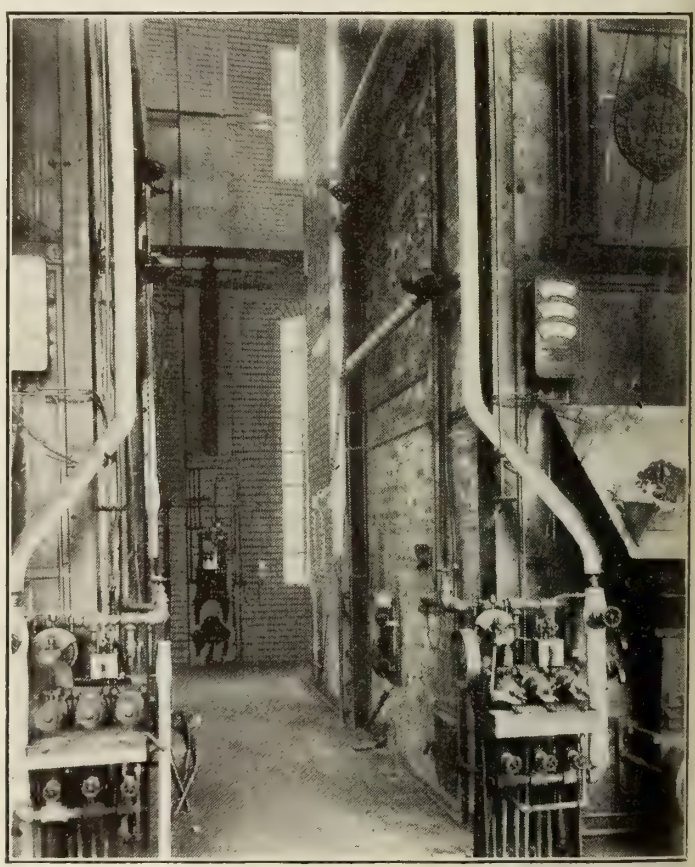
View of power house showing overhead bunker.

situated outside the building underground.

Each boiler is fitted with the Jones stoker, there being three retorts on each furnace, these stokers being made by the Underfeed Stoker Co. of Canada, the type used being the A. C. These stokers are operated by the Cole timing valve used by the Underfeed Stoker Co. the timing valve being operated from the fan engine shaft. The fan being controlled by the damper regulator, thus automatically slows down these stokers when it is itself slowed down by the damper regulator functioning.

The stokers have an area under each boiler of 6 feet by 9 feet in width. They are designed to give a rating of 200 per cent. for four hours, or a continuous rating of 150 per cent. On a basis of 13,000 B. T. U, per lb. of coal they are guaranteed to maintain an efficiency of 76 per cent. at 100 per cent. rating, 150 per cent. at 75 per cent. rating and 73 per cent. when operating at 200 per cent. rating. This is in accordance with the very best practice, and an efficiency of 75 per cent. at 75 per cent. rating is about as good as can be obtained under most conditions. Each boiler is fitted with a 5 unit valve-in-head Diamond [illegible].

Boiler fronts, stokers, weigh larry shoot, and ash conveyor riser in left foreground.



Looking between the boilers. Hay's CO2 Recorder and Draft Recorder on wall at back. The pipes on side wall are the Diamond Soot Blower connections. The three in one Precision Draft Gauge is seen just above coal hopper on boiler fronts, and the Cole timing valve for Jones Stoker is in foreground.

Recording and Indicating Instruments

Each boiler is fitted with a Precision Instrument Co. three point draft gauge. These instruments show at all times the draft over the fire, the air pressure in the tuyeres, and the draft in the last pass, or what is practically the chimney draft. Thus the fireman can tell at a glance just what the condition of the fire is, and any irregularity is detected as soon as it occurs. At the time of our visit the tuyeres pressure was showing 3.5 in. of water column, the draft over the fire was .1 while the chimney draft was about .6 inches of water.

There is also a Hay's CO_2 and draft recorder fitted on a pedestal at the back of the boilers right opposite the passage between No. 1 and 2 boilers. This is connected up so as to take reading from the last pass of all the boilers together, or can be shut off from any two, and concentrated on any one, for CO_2 readings. The same arrangement is made for the draft recording. In addition to these instruments the Bailey Meter Co. are installing a steam recording gauge.

The Steam Piping

There are two ways of reaching the top of the boilers, one by a stairway which is outside the dividing wall of the boiler room and pump chamber, the other by an iron ladder at the back of the boilers in the boiler room. The layout top of the boilers is one that is distinctly pleasing to the eye, and a model of compactness and efficiency. The installation of the steam piping was done by the Garth Company of Montreal, the expansion bends and main valves being supplied by the Crane Co. From the stop valve of each boiler a large diameter bend is brought over to the main header, which runs along the front of the boilers, an iron grating being installed which allows easy access to all valves and the boiler tops. The main header is supported on rollers, and is free to expand in either direction being anchored by the bends connecting it to the main valves. From one end of the header the main steam line is taken to the mill, and there is also a 5 inch main which goes down to the basement and in a tunnel over to the fire pump. From this five inch main a connection is taken near the boiler room floor, to supply steam to a Penberthy injector, which is installed as a standby feed. The pipe to the fire pump, which is a considerable distance from the boiler room, is carried in a special insulating and supporting conduit, supplied by the Rickwell Co., Cleveland, Ohio.

The photograph reproduced here will give the reader a very good idea of the piping arrangement, and he cannot help but be impressed by the neatness of it. The boiler tops are covered with Armstrong cork brick, and the piping covering is neatly finished off, pesenting a very smooth surface, with but little chance for dust to effect a lodgment. The monitor above the boilers in the roof can be adjusted to maintain a temperature sufficient to keep the boiler room comfortable in the hottest weather, while it can be closed altogether during the

winter months if so desired. The boiler tops are splendidly lighted by this arrangement, while the artificial lighting is effected by 100 watt lamps enclosed in special globes which act as reflectors and diffuse the light evenly. These lights are unusually good looking for a boiler room installation, and add a great deal to the general appearance.

The boiler tops in fact, enticed one to linger, instead of having the usual effect of hastening one's departing footsteps to a cooler and more pleasant region. Although two boilers were running the effectiveness of the insulation and ventilation was such that there was no inconvenience felt at all.

The Feed Arrangement

The feed arrangement consists of two Weir feed pumps and a Cochrane heater, in addition to the stand by injector already mentioned. The pumps and heater are situated in a recess at the end of the boiler room, right opposite the base of the stack, and the heater is placed on a concrete pier at a distance of about six feet above the suction of the feed pumps.

The pumps are each of 6 inch by 8½ inch by 15 inches in capacity, and are made in Canada by the J. & G. Weir Co. of Canada, Montreal, similar in every way to the pumps made by the parent company of Glasgow. Each pump is fitted with a counter by which the number of strokes can be checked up per hour, day, week or any other time required. They deliver the water to a main feed header running along the front of the boilers, from which a branch is taken off to each drum. Air vessels are fitted at the top of the delivery pipes which effectively cushion the pulsations of the pumps and give a steady smooth delivery.

The heater is of the Cochrane type, made by the Canadian Allis Chalmers with a heating capacity of 53,000 lbs. water per hour. It is supplied with a V notch, weir meter capable of handling 60,000 lbs. of water per hour. In connection with this meter there is an integrating, indicating and graphic meter for giving records and instantaneous reading of the amount of water being passed through the heater. The exhaust pipe leading to the heater is of 14 inches diameter, and is fitted with an oil separator, capable of purifying 185 lbs. steam per minute. The total water capacity of the heater is 115 cubic feet. The main suction of the pumps is 5 inches, and this is branched off to each pump.

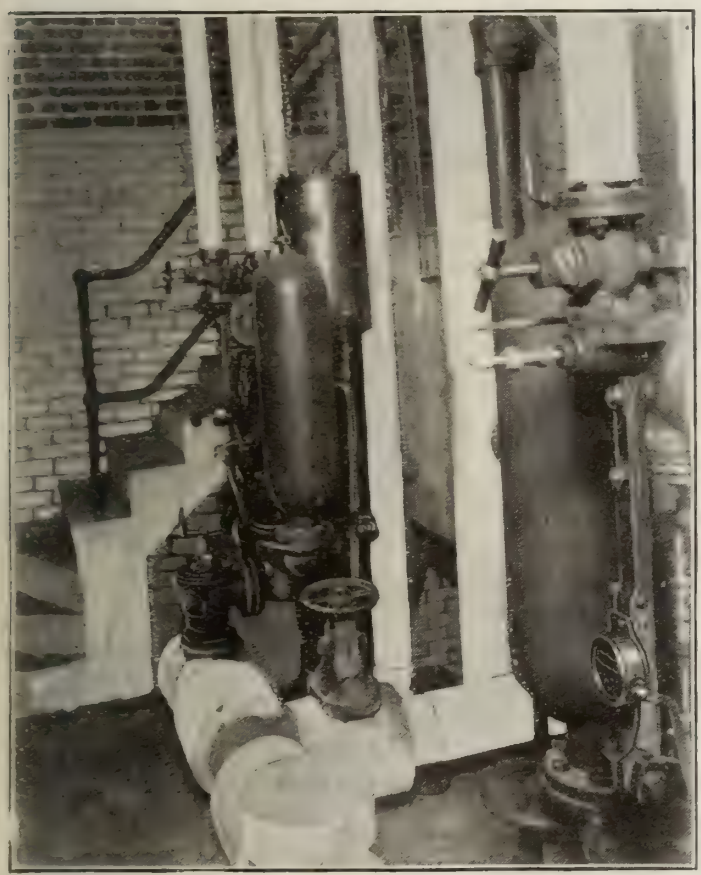
For use when the main heater is being cleaned there is a stand by hot well situated in the same recess and just alongside the main heater. This is of small capacity as it will only be needed at infrequent intervals, and at a time when the plant would be shut down.

This pump and heater room is closed off from the main boiler room by two doors, and when these are kept closed, the whole place is practically dust proof. It is lighted by side windows which can be opened for ventilation purposes when required. The fan engines and fans are just below, and can be reached by a ladder running from a grating back of the heater, the fan room in its turn being closed off from the main basement. The general effect is that the pumps, heater and fans are enclosed in a two storey concrete room, separated from the rest of the boiler room, and reached through well fitting doors.

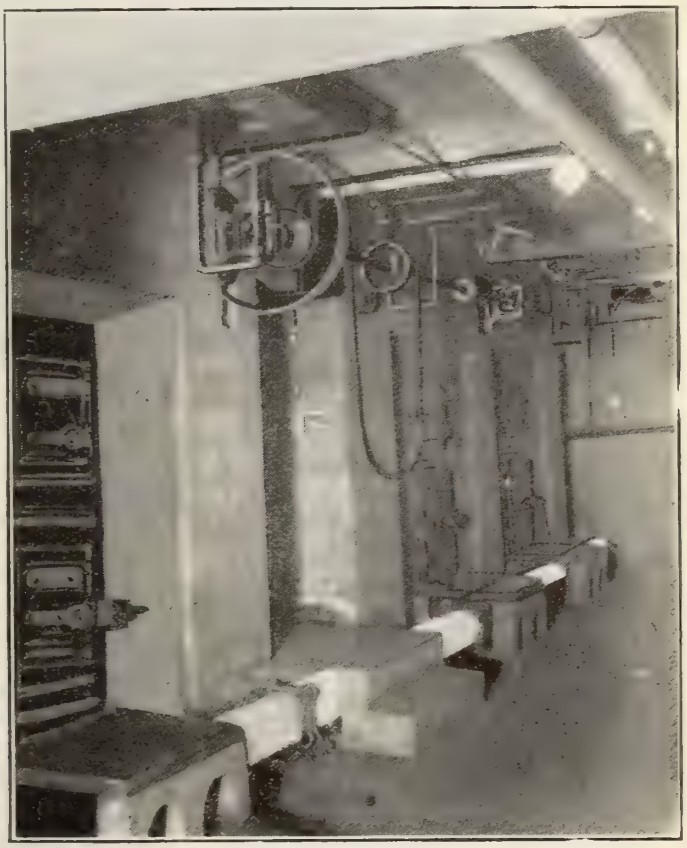
The Fan Arrangement

The air combustion is supplied by Sturtevant fan, driven by one of two engines, which can be connected to the fan shaft by means of flexible couplings, one engine being on each side of the fan. The fan is 160 inches diameter and the engines are 9 x 8 vertical high speed self oiling enclosed type. The fan delivers 33,000 cubic feet of air per minute at a static pressure of 5 inches water column.

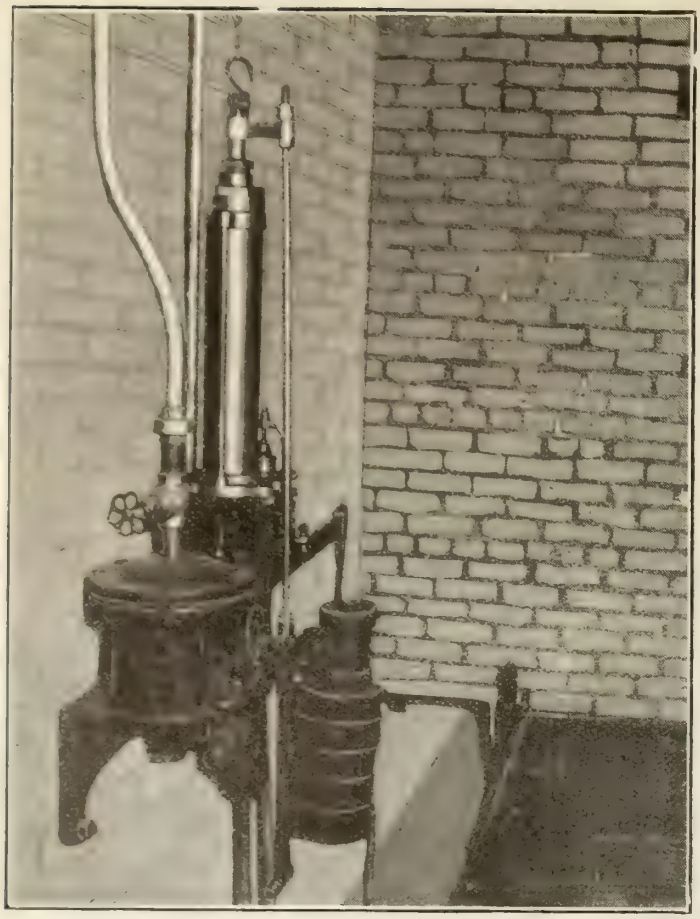
The fan engines are controlled by a Ruggles Klingemann automatic damper regulator, which is set to operate at a point just below the blow off pressure of the boilers, 125 lbs. The damper regulator is very sensitive, and effectually controls the pressure within the range of about 4 lbs. per square inch. The damper operates a valve in the steam supply to the engine, closing it down when the pressure approaches the point set for. The slowing down of the fan engine diminishes the supply of air to the stokers and as the timing valves are driven from the fan engine shaft, it also slows down the timers stopping the supply of coal and the supply of air at the same time. The damper regulator is set on the chimney wall, at the back of the feed heater,



Part of pump room and Weir Feed Pumps. The steps lead up to the heater platform.



Basement showing ashpit doors and ash conveyor piping. The countershaft driving the stoker timers up above the floor.



The Ruggles-Klingemann Damper Regulator. The grating is just above fan engines.

in the same room with the pumps.

Coal Handling Equipment

The power house is situated on a railway siding, so that the cars can run right up over the grating through which the coal is dumped. This grating is 12 inches mesh. and directly underneath it is the track hopper, which in turn leads to a reciprocating feeder, which delivers the coal to the crusher. This crusher is of the two roll type, 23 by 24 inches, and it crushes the coal to a suitable size for the stokers.

Leading from the crusher there is a bucket elevator conveyor, 10 inches by 6 inches having 62 feet centres which communicate with the overhead bunker and shoots to the travelling weight hopper. Thus the coal can be delivered into the daily service bunker until that is full, when it spills over a partition into the reserve bunker. From this reserve it can be dropped down a shute into the ascending leg of the elevator conveyor, and once more fed into the service bunker when required. The coal handling machinery is all electrically driven.

From the bunkers are chutes which communicate with a 1,000 lb. travelling weighing hopper, which in turn delivers the particular stoker hopper which requires it.

The whole installation of the coal handling machinery is by the Canadian Link Belt Co.

Ash Handling

For the ash handling in the boiler room basement, there is a steam conveyor or ash ejector installed by the Green Economiser Co. There are at present three intakes, one for each boiler installed, and these are situated at the mouth of the sloping ashpit in the basement. The conveyor pipe goes up at the end of the building, and discharges the ashes into a receptacle built in the same concrete tower that carries the reserve and service bunker. From this ash bunker chutes extend over the track, so that cars can be backed under them and loaded direct.

The operation of the whole boiler room is thus practically automatic. The coal conveyor can handle 20 tons of coal per hour, and the ash conveyor when in use can dispose of 200 lbs. of ash per minute, when the nozzle is supplied with steam at 110 lbs. per square inch. One man can very comfortably look after the whole outfit.

The plant is decidedly well laid out, and we cannot help but think that a man would be bound to take a pride in having such a job in his care.

The old power house of the mill, situated a few yards away, forms a very effective contrast, and should make the comfort of the present plant very apparent to anyone who was familiar with both of them.

The Erecting Engineer

The erection of the plant has been supervised for Mr. R. S. Kelsch by Mr. H. Piers. Mr. Piers has had an interesting career and is very much in earnest over his present occupation, and takes a pride in the plant which grows up under his skilled direction.

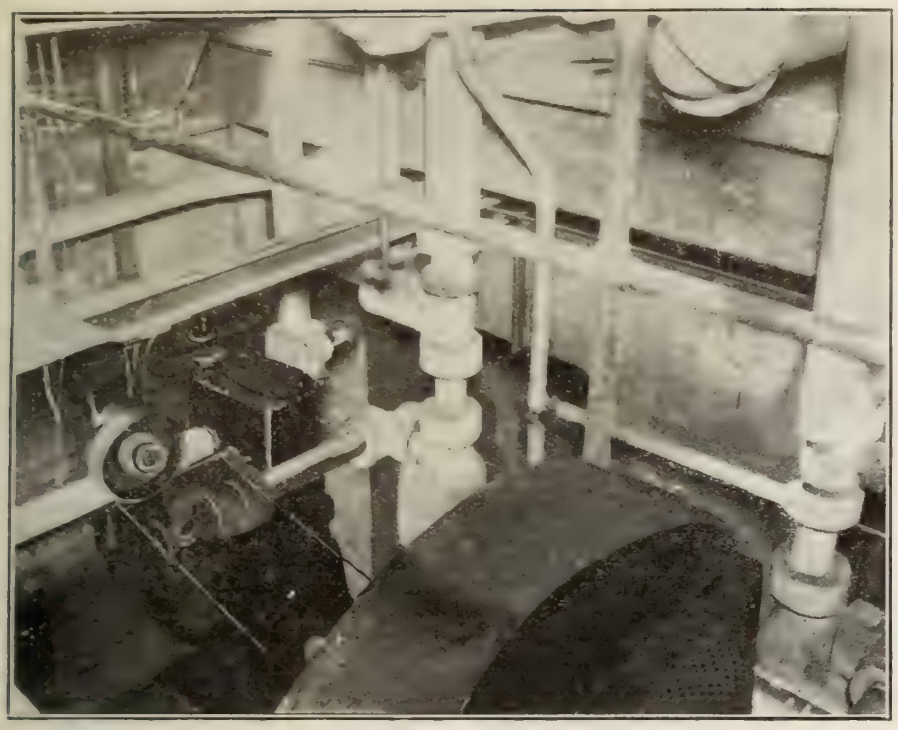
Mr. Piers was born in London, England, and educated at Kings College in that city. He served his apprenticeship with the firm of Humphrey, Tennant & Co., Deptford, and after his apprenticeship went to sea and sailed for a period of about nine years, obtaining the Board of Trade certificate of first class.

Leaving the sea he was employed on the superintending of new work for the British Government on the Tyne and Clyde, and continued at that work until coming to Canada.

Since that time Mr. Piers has been with Mr. Kelsch as supervising engineer of construction. His duties are to look after the carrying out of the specifications by the contractors, and when all is completed to his satisfaction, he starts up the plant, and gets it into thorough working order before handing it over to the owner's engineer.

It is a position that requires sound engineering and mechanical knowledge coupled with a considerable amount of

Partial view of Cochrane heater, showing the water meter.



Looking down on fan and fan engines. The grating was removed to obtain this view.

tact. Mr. Piers possesses these qualifications in marked degree, and we are indebted to him for the opportunity to thoroughly observe this plant for the benefit of our readers.

A STEAM TURBINE LOCOMOTIVE

Ever since the steam turbine—which was invented by Sir Charles Parsons in Great Britain—proved its wonderful advantage on board ship and for electric power generation, railway engineers have been looking forward to the possibility of applying it to locomotives. A bold experiment was recently made by a leading British locomotive factory, which constructed a turbo-electric locomotive, now being tested on the rail. The main turbine on this locomotive drives an electric generator which supplies power to four motors arranged in two groups on the front and the rear respectively of the locomotive. Each of these motors is capable of developing 275 horse power. One of the novel features of this locomotive is the condenser, in which the steam tubes revolve in water at a slow speed. The makers claim that this locomotive gives considerable saving in both fuel and water compared with the existing types.

View on boiler tops, showing main expansion bends. The bends at far end are on the feed pump steam pipes.

A 500 HORSE POWER ELECTRIC BOILER

To many people it will seem absurd to use electricity for making steam; but this is actually being done—and for a very good reason—on British railways. The railway systems in Great Britain are gradually being electrified where the conditions are favourable; and the result is that on certain routes steam haulage will be at work on one portion and electric haulage on another. The usual practice is to heat steam trains with the steam from the locomotive, and obviously this method cannot be continued when the steam locomotives are replaced by electric locomotives. Experiments have therefore been made with boilers heated by electricity, and tests made with one of 50 horse power have been remarkably successful. The efficiency of this system of heating is very high and the life of the elements is, owing to skilful design, very long. Plans are now being got out for a 500 horse power boiler, large enough to maintain the steam supply for a full size main line train.

SAFETY DEVICE FOR ELECTRIC HEATERS

One of the drawbacks of electrical appliances for heating water and other liquids is that if by chance the current is switched on while the utensil, such as a kettle or urn, is empty, the element gets overheated and is apt to burn out. In order to get over this difficulty some makers introduced a safety device in the form of a metal plug which melts at a comparatively low temperature and breaks the circuit, thus preventing overheating of the element. This method works fairly well but it has the objection that in order to bring the utensil into action again a new plug must be inserted. A British firm has therefore devised a safety appliance which is equally effective in action but which does not involve any part requiring replacement. It consists of a simple mechanical arrangement which cuts off the current when the utensil boils dry. All that is necessary to restore connection is to fill the utensil with water, when the device automatically re-sets itself.

Engineering Equipment Co., Limited, with offices at 619-23 New Birks Bldg., Montreal, have recently been appointed exclusive Canadian sales representatives for Schutte & Koerting Company of Philadelphia, manufacturers of the Koerting Low Lever Jet Condenser and a very complete line of power plant equipment.

The business is handled by four departments: Valve, Marine, Condenser and Jet and Chemical Department.

The University of Illinois Engineering Experiment Station, have issued bulletin No. 128, dealing with the ignition temperature of coal, the investigation being conducted by Ray W. Arms.

At the Bottom of the Temperature Scale

A Glimpse Into the Realm of Prodigiously Low Temperature Where Mercury Freezes to Stone and Ice is at a Fervent Heat

By RAYMOND FRANCIS YATES
(In "Tycos," Rochester)

THE VISITOR to the low temperature laboratory is shown a double-walled vessel containing a pale blue liquid seemingly impotent and harmless. Great mystery lurks within its limpid depths. It is boiling quietly, yet its temperature is several hundred degrees below that of the barren ice fields of the frozen North. This blue-tinted substance is liquid air. Its temperature is many, many degrees below the zero mark on a Tycos thermometer. When Fahrenheit put the zero mark on his temperature scale, little did he realize that it was several hundred degrees above the lowest temperature that would be produced by man. These wonderful facts concerning this apparently harmless liquid are interesting. Let us learn about it.

To the man who is not able to reason in scientific terms, the attainment of a temperature that reaches as far as 400 degrees Fahrenheit below zero is a seeming impossibility. These prodigiously low temperatures are produced every day in laboratories all over the world, and the method has been so simplified and perfected that it is a commercial reality which lost its speculative nature some time ago. The mere thought of a temperature as low as 400 degrees below zero is enough to stagger the imagination of the everyday man, yet the facts concerning the production of these low temperatures are easily understood.

Early in his career, Lord Kelvin discovered that if a gas was compressed and then allowed to expand freely through a small orifice, its temperature was lowered to a very noticeable extent. We can prove this by means of a very simple experiment, as all we have to do is whistle. When we do this, we compress the air within our cheeks and then allow it to expand through our puckered lips. If we place our hand close to our mouth, we can feel that the air issuing is quite cool, although it is hot when it leaves our mouth. If we could take that air which came through our puckered lips and put it through the same process again, we would find that it would become still colder. While it would be impossible for us to do this, machines have been devised that will do it and liquid air is produced to-day in large quantities by a machine that puts it through a continued process of alternate compression and expansion until it becomes so cold that it freezes to a liquid. In fact, if it is carried far enough, the air will not only be produced in the liquid state, but it will freeze to a white solid. The principle of producing liquid air by the "self-intensifying" process is easily understood. The air is first compressed to many thousand pounds to the square inch and then allowed to expand through an orifice. This expansion causes the expanding air to become colder, and this cooled air is circulated around the pipe bringing the compressed air. The compressed air is thus delivered at the orifice in a cooled condition. It then expands, causing further cooling, and this further cooled air in turn circulates around the compressed air pipe, making it still colder. The compressed air is thus continually becoming colder; the expansion produces more cold and by repeating this cycle uninterrupted, the temperature can soon be lowered so far that the expanding air becomes liquid.

Now that we have obtained an elementary understanding of the method of producing low temperatures, we will learn just what a wonderful thing a gas is when reduced to the liquid state. We are all acquainted with the fact that there are three distinct states of matter: solid, liquid and gaseous. We are also familiar with the fact that certain substances are easily changed from one state to another by simple means. Water, in its natural state and at normal temperature, is a liquid, but if we expose it to a temperature below the zero mark on a Tycos thermometer it rapidly becomes a solid and if we apply heat to it until it reaches a temperature of 212 Fahr. it becomes vaporous or gaseous. If we cool steam, it will immediately return to the liquid state, and this is true of any gas: if it is cooled it condenses and comes to the liquid state. Its tiny ultimate parts, which we are pleased to call molecules, crowd closer and closer together, depending on how much the temperature is lowered. If it is lowered enough, the molecules crowd so closely that they form a liquid and, if we have means to further reduce the temperature, they will crowd so close that a solid will be produced. Take oxygen, for example. Nature decrees that oxygen shall be a gaseous substance, but to be a gaseous substance it must have a specific temperature. If this temperature is either made higher or lower, the gas tends to expand or contract as the case may be. If we liquefy oxygen, we will have a very difficult time keeping it in its liquid state, since nature is constantly calling it back, it must have a certain amount of heat and this it subtracts greedily from its surroundings, leaving them comparatively heatless. Oxygen, when in the liquid state, is continuously boiling and vaporizing since it robs heat from everything with which it comes in contact, until it receives enough to return to its original state, a gas.

Now that we have come to understand just how low temperatures are produced, and the nature of liquid gases, there will probably be one dominating question in our minds, and that will be: "What will these liquid gases do; how will they affect other matter and what is their general behaviour?" This question opens the realm of romance in the study of low temperatures and liquid gases, since they perform many astonishing feats that are far removed from the common events of our everyday life.

If we drop a little water into a vessel of, say, liquid nitrogen, the water is instantly changed to ice and rattles around merrily in the nitrogen for a few seconds, since the nitrogen boils furiously when the water reaches it. This boiling continues until every bit of available heat is subtracted from the water or ice and then all remains quiet within the pale blue depths. In fact, if we dropped a piece of ice within the liquid, it would cause it to boil rapidly in the same manner! This fact causes no little wonderment in the minds of the layman, but it is easily understood. In the liquid gas we have a temperature several hundred degrees below zero, while the ice is just a little below zero, which, in comparison to the liquid gas, is warm; hot, in fact. From this it is also interesting to note that there is no such thing as cold. When we say that a substance is cold, we really mean that it contains only a small amount of heat. If a substance had absolutely no heat, the scientist would say that it was at "absolute zero." However, this goal has never been attained, although it has been approached within three degrees.

In our next experiment with liquid gases, we will drop a few elastic bands into a vessel of liquid air, and after the air has completed its period of boiling (it boils at 193 degrees Centigrade below zero), we will take the rubber bands out and examine them. We are quite surprised to see that they are frozen stiff, and if they were of the proper color, they would resemble macaroni that was in an extra dry condition. In fact, the rubber bands will be found to be very dry after they are removed from the liquid as it vaporizes as soon as it comes in contact with the outside air.

Our rubber bands, instead of being soft and flexible, are hard and brittle and will snap and crack if we apply pressure to them.

If a little liquid air is thrown upon the floor, there will be nothing left to mark the spot it struck but a little puff of white frost that rises and quickly disappears. If we examine the floor (no matter how quickly after the liquid strikes it) we will find that it is perfectly dry.

There are many more interesting experiments in freezing that can be performed with liquid air. If some of the substance is placed in a tin cup and the cup is covered up and connected to a vacuum pump, the liquid air will be evaporated so rapidly that the temperature of that which remains behind will be still further lowered, and, if the operation is continued long enough, we will find that a white solid substance will form on the outside of the tin cup. We might satisfy ourselves by assuming that it is moisture from the atmosphere freezing to the sides of the cup. True, some of it is moisture, but a large part of it is air which has been frozen to a solid mass! After all the air in the tin cup is vaporized, we will drop the cup on the floor or strike it a sharp blow with a hammer. To our surprise the cup will break exactly like a fragile piece of china. The explanation is that the cup became frozen and was rendered so brittle that it broke. The idea of freezing a piece of metal may seem rather remarkable to some people, but it is nevertheless true.

What would happen if we were to immerse our finger in liquid air? This is a very natural, as well as interesting, question. If we immersed our finger for the fractional part of a second, no harm would come of it, since the heat of the finger would cause the air to boil so furiously that it would not come in actual contact with it. If we left our finger in it until it got cold enough, and the liquid air actually came in contact with it, we could break our finger off much as if it were made of china. Would the finger return to its normal state? The answer is yes, from the standpoint of temperature and degree of hardness, but we would find that the finger would be absolutely lifeless from there on and would have to be amputated.

If a little mercury, similar to that used in Tycos thermometers, is dropped into liquid air, it may afterwards be used as a hammer, as it is frozen so hard that it will not lose its shape or be scratched. Flowers and all kinds of vegetation act in the same manner; they are frozen to a brittle solid.

If a bell were made of lead and immersed in liquid air, it would ring when taken out, much in the same manner as a bell made of brass.

What would happen if we were to drop a burning match into the liquid air? This question may appear absurd to the layman at first thought, but is it? Let us consider for a moment. We were taught back at school that oxygen causes things to burn. It supports combustion to put it chemically. We know then that we must have a considerable percentage of oxygen in our liquid air as the atmosphere contains a great volume of it. The question is, will the oxygen still support combustion when at this extremely low temperature? The answer is yes, very energetically. Instead of the match going out in the liquid air, we would find it to burn with almost explosive violence. Many materials and substances that will not burn in the atmosphere will do so in liquid air.

For the past few years scientists have been trying to reach the ultimate goal in low temperature work, and this goal, as previously stated, is what is known as "absolute zero." This has been calculated to be 273 degrees Centigrade below zero. A greater degree of cold cannot be obtained.

TESTING PETROLEUM PRODUCTS

The issuance of technical paper 298, "Methods for testing petroleum products, adopted by the Interdepartmental Petroleum Specifications Committee," is announced by the Bureau of Mines.

The methods included in this handbook are used officially in the routine testing and inspection of petroleum products bought under Federal specifications. They supersede similar methods published in Bulletins 1 to 5, inclusive, of the Committee on Standardization of Petroleum Specifications.

The Interdepartmental Petroleum Specifications Committee was formed under authority of the Bureau of the Budget, dated October 10, 1921, and an Executive Order, dated November 8, 1921. It replaced the Interdepartmental Committee on Standardization of Petroleum Specifications, which in turn superseded the war-time Committee on Standardization of Petroleum Specifications. The work of the several committees has been continuous, and the present set of testing methods is the result of several years' experience in preparing specifications and drawing up testing methods for petroleum products.

The present set of testing methods was prepared by the Technical Committee on Standardization of Petroleum Specifications and adopted by the Interdepartmental Committee on Standardization of Petroleum Specifications, which were the immediate predecessors of the present committee.

The paper includes information regarding color tests; cloud and pour point determinations; viscosity tests for fuel and lubricating oils; melting of paraffin wax, distillation of gasoline and kerosene; flash point determination; burning tests for kerosene; long-time burning oil, mineral seal oil and signal oil; determination of water; emulsion tests; determination of sulphur; the doctor test; corrosion tests, etc., etc.

Technical paper 298 may be obtained from the Bureau of Mines, Washington, D.C., one copy being distributed free of charge to an applicant. The paper is obtainable in quantity lots from the Superintendent of Documents, Washington, D.C., at 10 cents per copy.

THE POWER EXPOSITION

Announcement has been made of the National Exposition of Power and Mechanical Engineering to be held at the Grand Central Palace, New York, from December 7 to 13, inclusive, (except Sunday intervening) by the managers of the Exposition.

The Exposition was decided upon by a group of engineers and manufacturers who had felt the need for such a means of having men get together, exchange ideas, see the latest development in equipment, and lay problems before the manufacturer.

The business opportunity where a manufacturer may meet a large assemblage of power plant and mechanical engineers and capitalists interested in power, is significant to firms keen for such business. A number of progressive manufacturers have already engaged space for their exhibits.

The Exposition will immediately follow the annual meeting of the American Society of Mechanical Engineers and it is expected that the exhibits will supplement the programs and discussions at the professional meetings of the Society. The Professional Divisions of the Society will hold sessions relating to fuels, stokers, steam power plants, railroads, steam utilization in the paper industry, textile and gas power, and it is expected that the exhibits at the Exposition will throw interesting light on the papers presented at these sessions of the A.S.M.E. meeting.

That the Exposition will be comprehensive may be inferred from the plans which are to include exhibits of every type of machine, apparatus, equipment, instrument, device and the various materials and supplies necessary in the operation of the complete power plant. The committee decided that its keynote should be "an Exposition of apparatus employed in the generation, distribution and utilization of power."

The advisory committee for the Exposition, under the chairmanship of I. E. Moultrop, of the Edison Electric Illuminating Company of Boston, is comprised of: Milan R. Bump, president National Electric Light Association; N. A. Carle, vice-president and general manager Public Service Production Company; A. G. Christie, professor mechanical engineering, Johns-Hopkins University; Fred Felderman, national vice-president, National Assn. of Stationary Engineers; E. B. Katte, chief engineer, motive power, N.Y.C.R.R.; Dexter S. Kimball, president, The American Society of Mechanical Engineers; Fred R. Low, editor "Power"; David Moffat Myers, of Griggs and Myers, Consulting Engineers; Calvin W. Rice, secretary, The American Society of Mechanical Engineers; and the managers are Charles F. Roth and Fred W. Payne, with offices in Grand Central Palace, New York, to which all requests for fuller information and reservation of space should be made.

Bulletin 73 of the Kwanee Boiler Company, Kewanee, Ill., describes their Kewanee horizontal return tube boiler for power purposes, and also their Kewanee smokeless tubular boiler with down draft furnace and steel casing. Complete specifications and particulars are included in the bulletin, and also the Century rocking grates.

The Staff Have A Discussion on Combustion

How to Get the Best Results From a Mixture of Wood and Coal Was the Point—See How These Practical Men Present Their Arguments

By "JOHNNY SHOVEL"

This is the first of a series of articles on the practical operation of boilers by a man well qualified to speak on the subject. He is writing them in plain language, and avoiding technicalities. There will be a fund of information found in these articles for all classes of engineers.

IN THE days when we were young it was the usual thing among families of modest means to send boys who "liked machinery," to learn a trade. After the ordinary school, that was all the education the "old man" could afford to give us, and when we started in, we worked for experience and darned little else.

But that was better than my dad had it. His father had to "pay a premium" to get him apprenticed. That is, he gave the firm to which my dad was bound, fifty dollars to start him in, in their shops. I don't remember whether the fifty covered it all or had to be paid yearly. I do know that in my time, apprentices worked the first six months without pay, and for six months after drew the useful sum of $2.50 per week. Very different from the present day.

My own particular tastes brought me under the dominion of the master mechanic of a ramshackle plant in which railroad cars were built, and there is not the least shadow of a doubt that in his gang we got experience all right.

We were a helper. We helped the belt man fix belts and the oiler to oil. We gave a hand to put up shafting, and we helped make foundations and afterwards to put the machines on them. For the electrician we crawled around on the roof timbers of the foundry, said timbers being particularly well loaded with dust, so that we got almost stifled with it in combination with the grease and wood smoke from the moulding floor below.

That company had grown and overgrown and its shops had been put up helter-skelter, any old how, whenever they had need of a new one. There were six engine rooms, each with a man in charge, besides fan engines and a hoist or two. We had five boiler rooms scattered around the plant to make the necessary steam. Every time a man "took a day" the gang would be juggled around to keep things going, and we would be sent to fill in according to our ability.

Being "willing" we got a chance to try our hand at a number of things.

Some days (they seemed years) we fired at the mill, where there were four big R.T. boilers. The mixture was shavings, sawdust, and when necessity compelled, a little soft coal slack to keep her going. The shavings were handled by a blower. But for some reason or other, they were not fed straight into the furnaces. They dropped into a brick compartment at one end of the boiler room, and from there we had to shovel them to a pile in the middle of the floor, and then shovel them again into the furnaces.

Under the conditions, firing one of those boilers was like feeding an elephant with strawberries, strenuous work for the results. The company had such a time keeping men on the job, they simply had to think about making changes. A great many schemes were discussed and the advantages and drawbacks to each kind of furnace well considered.

He Liked Dutch Ovens

The engineer at the mill favored "Dutch ovens," and he used to tell us what a soft time the firemen would have when he got one built in front of each boiler. "The stuff that comes in to us is about half water," he said, "that has to be dried out before it will burn. Now the roof of a "Dutch oven" can be made hot by firing good dry stuff for a while. Then when it's good and hot, you can start giving her the stuff as it comes. You have 'perpetual motion' just as long as you keep the supply somewhere under the drying ability of the roof, because the heat from the roof dries the wood, and heat from the burning wood keeps the roof hot, so there is more heat to dry the next lot of stuff that comes along! When you are firing this stuff you got to have plenty of room, so we will make them good and big, and put in big grates, because there 'aint much heat in the stuff we get. Most of the time you have to handle more than two ton of it for the same quantity of heat we could get out of a ton of coal, if they would give it to us.

"The grates will be slantin' to the boiler, so the shavings and sawdust must roll down the incline and will not be able to gather in heaps, same as they do on us in these blamed little furnaces. You know what happens if you work hard and get a pile under one of these boilers. Only the outside will burn, 'cause that's the only part that gets any air. On the inclined grates, the stuff will not get too thick at any one point, and the air will get through the bars easy. With these grates, and the stuff coming in through the chutes straight through the roof of the furnace, the outfit will be self-feeding. No more back-breaking shoveling when we get our "Dutch ovens'."

A Counter Opinion

The engineer at the blacksmith shop was skeptical. "When you get those big furnaces in your boiler house, you have very little room to work them, much less repair them," was his verdict. "Sometimes you have to fire with coal, 'cause there is not enough stuff coming in from the mill to keep you going. Then, my lad, you will find that those wonderful big grates of yours are mighty hard to keep covered. Unless you are darned careful, you will get too big a fire or a bunch of holes. They cost money to build, those 'Dutch ovens'. The roof arch

is so wide that it exerts a tremendous pressure on the bricks which are in it, and unless they are the very best they are likely to spill off when the temperature is high, so the roof soon falls. You got to get bricks which will stand pressure at temperature and then put plenty of 'buckstays' on the sides so the walls will not bulge out and drop the roof into the furnace. A saw mill can use them and get satisfaction, 'cause they always have the same kind of fuel. You have to burn coal sometimes and you want a furnace which will burn shavings or coal, or a mixture of both, with equal success.

"A little more combustion space under your present boilers will do the trick. The best way you can use your brick is in building a higher setting. While at that you can extend the front far enough to get the chutes to discharge straight into the furnace. Then you are ready for any fuel."

What Joe Thought

Joe Le Blanc at "the factory," was burning shavings and sawdust, but the stuff that came to Joe was from wood that had at least been air-dried and most of it kiln-dried, and it was burned under Babcock and Wilcox boilers.

"Wid dese B. & W. boiler de shavin' from dis factory she is burn easy. Dar is plenty space between de gratebar an de tube. You boiler she set down so close to dose grate dar is no room for burn, no place for what you call combustion. De flam is long when wood is burn, and if you let him hit de cold boiler plate he is put out and an' do not make de big heat. You mus' be careful.

"My boiler, she is set twice more high dan you boiler. De shavin' have a long draw, so long, be gosh, dey 'aint hit dose grate at all. Look at dem. De front is bare, hardly nothing on dem, 'cept at de bridgewall. All burn while dey in de air, so plenty air for first class combustion. Plenty air is de whole business for if de fireman is feed too fast, at first de pressure go up, and den when de shavin' begin to pile, go down 'cause de air can't get thro' de pile an' only de outside is burn. You watch dat firemans, every time de steam go up a little he is cut off de stuff.

"Before dis job I was engineer, me, for a factory where dey make de house trim, flooring, sash an' door an' all dat kind of thing. We make de 'Dutch oven' in dat place, but we also take dem down ourself, too. Dey burn too much. All de shavin' an' some coal. Dats de first place I try dis plan. An you see dar is no coal burn here. In de winter tam all de surplus shavin' fall in de corner for de night fireman, who fire by hand."

The "cyclone" at Joe's place of toil was arranged to discharge into a big galvanized tank. The usual thing these days. This tank was directly above the boiler room and the chutes carried the stuff straight to the boilers, or, when the supply exceeded the demand, to a large brick room where it was stored against a time of need. In that store room he had a pipe from the blower, and all they had to do when they wanted stuff from there, was to get in and feed it to that pipe and let the blower shove it up into the gal. tank again. There was also a door in the "corner" through which the fireman could shovel the stuff, and by that door the night man in winter got his because the blower didn't run at night.

It cost something to build according to the requirements of the insurance company, but Joe's store room with its thick walls enabled him to save so many shavings when there were plenty being made, that he didn't have to burn any coal at all.

"What kind of grate? Well, I try everywhere to get some grate to suit dis stuff. Nobody have dem, what I want, wid holes taper, big underneath, and half de size inside de furnace. So I get me a nice piece of white pine, and have feller in de shop shape it. While he do dat, de blacksmit' is making me a special drill taper, for de taper holes. My idea is to have de air travel fast tro de holes and pass well into de fuel. De small stream will pass furder 'cause it's fast, and hole of dat shape hard to block, 'cause the air so fast it blow de shavin' out, or else dey fall tro de taper hole."

Some of the boys who visited Joe were used to firing coal only, and they found it hard to believe his theory of the partly bare grates. Joe explained that while he went to all kinds of trouble to get the air through his bars, really very little came through where the stuff was actually piled on them hardly more than enough to keep them from burning. Therefore the air for combustion must come from the front and since the supply through the firedoors was not enough, he arranged his chutes so the stuff would fall well towards the bridgewall and leave part of the grates uncovered, so the required air could get in. He didn't allow the shavings to blow into the furnace because the blast would burn up the grates. They dropped by gravity, and he could control the supply of air by the ash doors.

A CORRECTION

The article in May 5th issue, entitled "Boiler Explosion at Bridgeport," was wrongly credited to the "Traveler's Standard," instead of the "Locomotive."

BULLETIN

The Crane Packing Co., 1800 Cuyler Avenue, Chicago, have published a very interesting little book on the metallic packing of condensers. While the book is frankly intended to advertise the packing made by the firm publishing the book, it contains a good deal of interesting information on condenser tubes not generally available. There is a short article on condenser tube disintegration, with illustrations, one on condenser tube deformation, also illustrated, and two microscopic photographs showing the structure of both hard and soft tubes. There are in addition descriptions of electrical chemical and voltage tests to determine the liability of tubes to corrosion.

BULLETIN

A bulletin has been issued by the Goldie McCulloch Co. of Galt, describing the V-type Rees Ro-Turbo pump, for services up to 1,000 Imperial galons per minute. These pumps will deal with liquids of a viscous nature, such as thick oil, sugar, etc. An illustration of the pump with the top half of casing opened up is included in the bulletin, and the necessary information required by the company for quotations is indicated.

THE OLDEST ENGINEER

Mr. Alfred Ablitt, who is an engineer in the Consumers' Gas Co., was recently presented with an illuminated address by his fellow engineers in the company. The occasion was the completion of his fiftieth year in the employ of the company. Mr. Ablitt is said to be the oldest engineer in the province of Ontario.

Several contracts have been awarded for additional work to the Cambridge St. school, Ottawa, totalling $55,000.

Refrigeration For The Power Plant Engineer

The Expansion Valve and Its Function. The Direct Expansion and Brine Methods of Cooling Are Briefly Described, and Tables of Salt Solutions Given

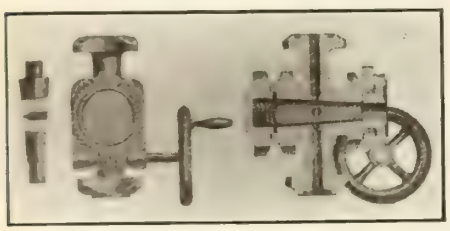
By T. H. FENNER

THE LAST point reached in the study of the mechanical refrigeration system was the liquid receiver, the course of the ammonia gas and liquid having been traced from the compressor to this point. The next important point in the circuit is the expansion or regulating valve.

The Expansion Valve

The function of the expansion valve is to pass ammonia at high pressure through a small opening into the low pressure side of the system. The liquid passes from a pressure of from 125 to 175 lbs. into a pressure of 15 lbs. to 25 lbs. The valve is capable of very fine adjustment, as it is upon the amount of liquid passing this valve that a great deal of the successes of the system depend.

It is a common statement that the ammonia liquidation passing the expansion valve "flashes into gas." The ammonia liquid does not flash into gas immediately, but passes to the low pressure side of the regulating valve as a liquid. If there is not the necessary heat available on the low pressure side of the system to evaporate it it will remain a liquid. Also when it arrives at the low pressure side it is at a temperature corresponding to the temperature on the high pressure side, and before taking up heat to transform it into a gas it must give up some of its temperature to the brine or surrounding air, till the temperatures are equal. When this is



Expansion on Regulating Valve

done, it will take up heat to supply the necessary latent heat to make the transformation from liquid to gas

A typical regulating or expansion valve as used by the De La Vergne company is illustrated. It will be noted that the opening of the cock is accomplished by means of a worm and worm wheel, thus allowing the most delicate adjustment. In other types a graduated wheel is used, the plug of the cock having a pear shaped or diamond shaped opening, allowing very delicate shades of adjustment.

The result of passing too large quantities of liquid through the expansion valve would be to have liquid remaining in the coils when the suction side of the compressor is reached, there not being sufficient heat available in the cooling chambers to evaporate the liquid passing through. A too wide opening, carried to the extreme, would naturally result in the pressure in the high and low side of the system being equalized. Another effect of a too rapid flow of liquid would be an intense cooling effect with formation of heavy frost on the pipes close to the expansion valve, thus forming an insulator which would prevent the liquid being evaporated until it had passed the point of frost. In this way the coils would gradually become flooded, as mentioned previously.

The Liquid Trap

Before the gas enters the refrigerator, it is passed through a trap which precipitates any oil or liquid still remaining in it. This trap is placed between the expansion valve and the refrigerator and saves any foreign matter from reaching the coils. This trap is provided with means of cleansing or draining, and should be carefully watched and attended to regularly. Lots of trouble arises on refrigerating systems, through some neglect of the oil separators and liquid traps.

The Direct Expansion System

The direct expansion system, as its name implies, is one where the ammonia coils are placed directly in the rooms to be cooled. The heat is then absorbed directly from the contents of the room by the evaporating liquid. These coils may be placed on the side of the room or on the ceiling, while in some cases where the material to be cooled is liquid, the double pipe system is used, in a similar way to the double pipe condenser. There is a modification of this in that the pipe containing the liquid to be cooled is made in corrugated form, in order to prevent liability to bursting should freezing occur.

The amount of coil surface required will vary with the temperatures to be maintained. In cooling rooms by evaporating ammonia liquid in coils the latent heat of the liquid as well as the difference in temperature is utilised. There is usually a difference of about ten degrees between the temperature of the room and the temperature of the gas in the coils. The usual proportion of cooling surface allowed in freezing tanks is from 40 to 50 square feet of external pipe surface to each ton of refrigerating capacity. This will mean about 150 linear feet of 1 inch pipe, or 100 feet of 1½inch pipe and 80 feet of 2 inch pipe.

The Brine System

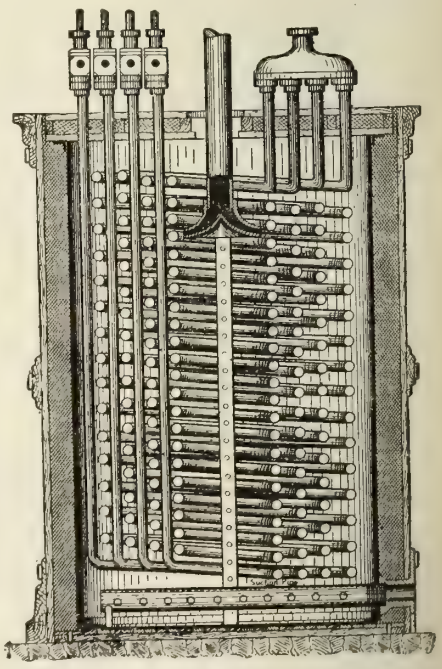
With the brine system more apparatus is required, including pumps for circulating the brine, and tanks for storage as well as the actual brine cooler itself.

The brine itself is a solution of chloride of calcium, or chloride sodium (common salt) and water. This solution has a very low freezing point. The chloride of calcium brine may be made of such density that its freezing point will be minus 54 degrees, or 54 degrees below zero, while the salt solution has a maximum density. Chloride of calcium brine has also the advantage that it is not corrosive.

The Baume scale is the one used to determine the specific gravity of the mixture, a graduated weighted bulb and tube being used. The height of the bulb and tube afloat in the solution gives it specific gravity. The tables herewith give the properties of both the calcium and brine solutions.

The brine cooler may be of the double pipe type, or it may be of the submerged type, the ammonia coils being submerged in the brine. The brine is often kept in circulation in the brine tank by an agitator, to ensure all parts of it coming in contact with the coils. The suction of the brine pump should be kept above the bottom of the tank so that it does not get clogged up with any solid matter that may have come to rest on the bottom.

If a large quantity of brine is kept in a storage tank, there is a considerable reservoir of refrigerating effect, and it is often the practice to keep rooms cool at night by circulating brine that has



Circular Brine Tank with four ammonia coils. Brine is drawn off through perforated pipe in bottom of tank. An expansion valve is fitted to each coil.

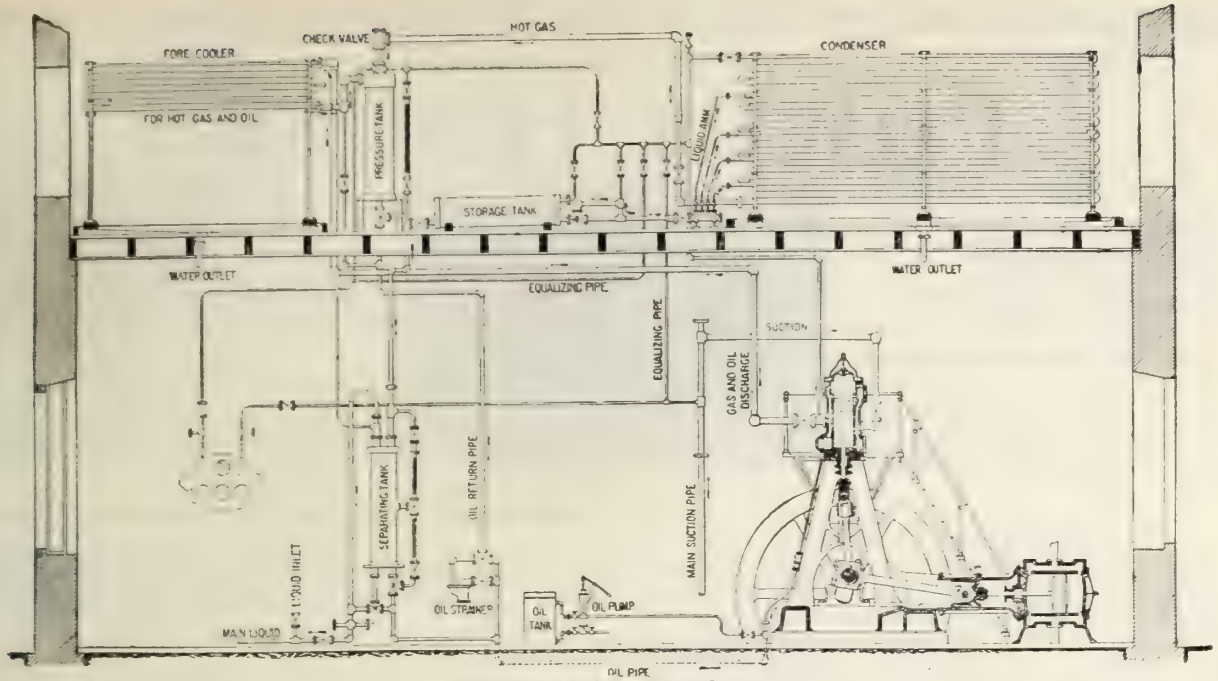


Diagram of Refrigerating Plant.

been cooled during the day when the machine was running.

An indirect method of cooling by brine is to place the brine tank underneath the ammonia coils, and to pump the brine in a spray over the ammonia coils. The whole arrangement is placed in a separate insulated space, and the air from this space is pumped through the room to be cooled, much in the same manner as air is used in the indirect heating system.

In using the brine system, more coil surface must be used for the ammonia, the proportion being about 50 per cent. more for brine than for direct expansion.

CHLORIDE OF SODIUM BRINE

Degrees on Salinometer	Pounds Salt per gallon	Freezing Pt. Fahr

We have illustrated here a diagram of a complete refrigerating plant the evaporation or suction side only not being shown. This may be either direct or brine system.

We shall take up in our next article the absorption system of refrigeration. This system is not nearly so well understood by the average man as the compression system, and there are not very many o fthem in Canada comparison with the compression machines. However, there are enough of them in use in this country to make their study necessary for any one who claims to understand refrigerating machinery, and we shall therefore give a general description of them with perhaps a little more detail than has been given of the compression plant.

CROSSED BELTS

The Editor,
The Power House.

Dear Sir—The writer desires to point out an error in the fourth paragraph of an article by Mr. John Thorn on page 32 of your May 5th issue, regarding the length of a crossed belt.

The Rule given for finding this length should have read:—

Add together the diameters of both pulleys, divide by two and square this quantity, also square the distance between centres and add to the first square. Extract the square root of the above sum and multiply by two. Add to this half the distance round the outside of both pulleys.

Example:—Suppose a belt travelling crossed over pulleys two and four feet in diameter at ten feet centres. The length of this belt is obviously well over twenty feet.

By Mr. Thorn's formula we get the length to be:—

$$[\sqrt{(4^2+10^2)}-10]2+(4+2)\ 3.1416 = 20.38.$$

By the rule as given above we get a length of:—

$$\sqrt{\left\{\left(\frac{4+2}{2}\right)^2+10^2\right\}}2+\frac{(4+2)\ 3.1416}{2} = 30.2$$

It can be seen at a glance where the error is.

It might be here noted that the rule for open belts is identical with the above, except that you start by taking the difference between the diameters of the pulleys instead of adding them.

Yours etc.
ENGINEER

Member of the Audit Bureau of Circulations

Super Power Stations

EVIDENTLY all the huge steam electric power generating stations are not going to be located in the United States, judging from the account of the plant now being erected in Manchester, England. The first section of this station will contain turbo generators for the supply of 90,000 kilo watts, which will be generated at 6,600 volts, 50 cycle three phase. The transformer rooms for stepping up to 33,000 volts for transmission purposes are located in a separate building running parallel with the turbine room. This station is particularly well situated both in regard to an amply supply of circulating water, and facility for handling coal supply. The site covers 13 acres on the banks of the Manchester Ship Canal, and a special embankment has been made for the coal barges, which bring coal from collieries only four miles from the station, by way of the Bridgewater Canal, a small canal adjoining the large one.

The boilers for this station are Babcock & Wilcox, containing 16,000 square feet heating surface, and placed back to back, making them double ended from the firing point of view. They will generate steam at a pressure of 375 lbs. per square inch, and will be fitted with superheaters, steel tube economisers, and balanced draught regulation. The condensers will each have an area of tube surface of 40,000 square feet, and the weight of each condenser without the tubes will be 50 tons.

The culverts for the supply of condensing water, which will be drawn from the ship canal itself, and returned to it, are of such size that they will allow for the flow of 7½ millions of gallons per hour. This is an enormous quantity of water, and it shows the prime necessity of a station of this kind being located where water is easily available, and to be obtained for the cost of pumping only. This amount of water would be sufficient to supply the needs of a city of 750,000 people.

In order that the circulation of such a quantity of water will have no effect on the ship traffic, the inlet and outlet is arranged to take place over a large area, and in such a way that the outlet is discharged below the surface of the water. In the outlet chamber there is a long central weir, for measuring the amount of water used. These inlet and outlet culverts are driven directly through the red sandstone rock which forms the foundation of the station. This station is one of the first of the proposed super-power stations to be erected in England, and it will be interesting to see later on how its performance compares with that of the large stations in the United States. The proximity of the coal fields and the water haulage should make for a cheap fuel supply.

Steam electric stations in England had a very low cost per kilo watt hour in pre war days, when coal was cheap, and labor normal. Both coal and labor are at higher rates now than in those days, and it will be interesting to see how the large stations will compare with the performance of those earlier days.

The city of Manchester possesses a number of interesting stations, but this will be the shining light for them all when completed.

Special Certificates

THE MEMBERS of Ottawa Lodge C.A.S.E. have forwarded a protest to the Board of Stationary Engineers, against the attempt of some party or parties to have special certificates issued to firemen or engineers in small factories such as cheese factories and dairies. The special certificate is asked for in places where no more than seven persons are employed. The request is said to embody a lowering of the experience necessary, and also a reduction in the fee for the examination.

The first glance looks like an attempt to get around the provisions of the stationary engineer's law, and admit men who could not otherwise qualify. However, looking more closely into the matter, the idea may not be so dangerous as at first appears. As a general rule, these dairies, cheese factories, small canning factories, etc., are only working for a limited period of each year, and it may be a matter of some difficulty to obtain a man with the necessary qualifications to operate them for the limited period. The apparatus usually consists of nothing more than a boiler, and perhaps a small engine, the auxiliary apparatus being limited to a pump or injector.

It is of course necessary that the man who is to operate these appliances shall be acquainted with them sufficiently to make him a safe operator, but it does not require any great length of experience to ensure this. There is apparently no attempt to have totally unqualified men operate them, but the object of the request would seem to be to enable a local man, who would always be available to operate when necessary.

While we are in entire sympathy with the regulations being rigidly enforced, it seems that in this case too narrow a view might work unnecessary hardship on a class of small manufacturers, whose profits are none too great at any time. We may be wrong in our estimate of the situation, based on the account in the daily press. If so we should be glad to be corrected.

From our knowledge of the type of plant in question, what is really required is a much more rigid inspection law than the one now in force. Many of these boilers are in a state bordering on decrepitude, and it is very difficult to impress on many of the owners the danger of allowing the boiler to deteriorate to such an extent. We have seen some pretty bad cases, and these made us think that there must be many more in worse case that no one ever inspects.

In this direction there is undoubtedly room for improvement.

Management of Direct Current Machinery

By M. BARRY WATSON
Director of Engineering, Toronto Technical Schools.

PRACTICALLY all electrical machines have self oiling bearings. The smallest ones are generally oiled by means of a wick, one end of which rubs on the journal, the other hanging in an oil well. The usual type of bearing oiler on the larger machines consists of two or more rings which hang over the journal, passing through grooves in the bearings, their lower sides hanging into the oil well. As the shaft revolves, these rings revolve with it, carrying oil from the well to the bearings. With properly fitted bearings and good oil there should be absolutely no trouble with these. This is one cause, however, of neglect of the oiling system, and sometimes a hot box or warm bearing causes disastrous results, whereas it could have been avoided by a periodical inspection of the bearings.

The oil wells must be kept full enough for the rings to dip into the oil, but must not be too full or oil will be thrown out along the shaft. Some machines have overflow holes to prevent filling too full. These should of course be kept clear. To prevent the oil creeping along the shaft under normal conditions, a collar is turned on the shaft which throws any oil which travels that far into the overhanging part of the bearing housing and cap, from where it runs back into the oil well.

The oil should be changed about once in six months for a normal amount of running, or oftener if it becomes dirty or causes the bearing to heat. New oil should be strained if it appears to contain any foreign matter. Only the best grades of dynamo oil should be used, as they are specially made for electrical machinery. In an emergency, however, any good grade of engine oil may be used temporarily, with little chance of damage being done. The oil wells should be thoroughly drained and washed out with gasoline before new dynamo oil is put in.

If oil is to be used a second time, it should be filtered and allowed to cool. The bearings and oil wells should of course be kept free from dirt and grit at all times. When cleaning or other work is being done on other parts of the machine or in the vicinity, the bearings and oil holes should be protected from dirt.

For large turbo-generator sets a closed oiling system is used in which the oil is pumped into the bearings with sufficient pressure to float the journals on a film of oil. The oil pressure is generally supplied by a pump geared to the turbine, but an auxiliary pump must be used when starting, as the revolving parts are so heavy that all oil is squeezed out from the bearings when the pressure is not on, and if the machine were run in this condition the bearings would be ruined.

Hot Boxes

A warm bearing or "hot box" may be caused by any of the following conditions, the remedies for some of which are given, remedies for the others being obvious:

1—Belt too tight.
2—Lack of oil in oil wells.
3—Oil rings jammed or not revolving.
4—Dirt in oil, or poor grade of oil.
5—Too tight fitting of journal boxes. (Remedy.—Ease off the cap bolts, and when the machine is shut down either put an extra shim under the cap, or scrape the bearings to fit properly.)
6—Rough surface on the journal. (Remedy.—A new shaft, as straightening can seldom be done successfully. If the bend is close to the journal, the latter can sometimes be turned down to a smaller diameter concentric with the straight part of the shaft. This requires special equipment to which most engineers have not access.)
8—End thrust of the revolving part. (Remedy.—If this end thrust is due to improper levelling of the machine, it may be re-levelled. If due to magnetic pull, it is a factory job, although some relief can be obtained by setting the axis out of level sufficient to compensate for this pull at an average load condition.)
9—Excessive side pull, due to armature not being central between field poles. The same effect as a too-tight belt. (Remedy.—The bearings should be relined with equal clearances between armature and all field poles, or the field poles may sometimes be shimmed out from the frame with sheet iron or sheet steel shims the full size of the field core.)
10—Bearing at pulley end worn out of line by pull of belt. (Remedy.—Reline the bearings.)

If a bearing becomes hot while running, feed it with heavy oil, loosening the cap bolts slightly and slackening the belt as much as possible. If this does not prevent further heating throw all load off the machine, but keep it running slowly with plenty of heavy oil until it is cool. This is to prevent the bearing freezing. Never try to cool a bearing with water, as this is most likely to freeze it. A frozen bearing can sometimes be loosened with kerosene. The oil wells will, of course, require cleaning out before the machine is again started, and a liberal application of new oil applied.

A new machine should be run for a few hours without load and at slow speed if possible, before being put into service to see if the bearings are all right.

Oscillation of Rotating Parts

Belted, geared or engine-driven machines are generally found to oscillate more or less regularly along the axis of the shaft, if properly levelled, due to external forces. A motor-generator, or rotary converter on the other hand tends to assume a fixed position with relation to the bearings. When no oscillation takes place grooves are likely to be worn in the commutator or collector rings and shoulders on the journals, thus demanding more care and careful inspection.

A mechanical oscillator is sometimes provided to insure the oscillation of the rotating parts along the line of the shaft. The simplest type of mechanical oscillator consists of a steel ball and circular steel ball race, backed by a spring mounted opposite to, but not quite parallel to, the end of the shaft. The machine is installed not quite level so that the shaft tends to move toward the end where the oscillating mechanism is

mounted. The ball race is so adjusted that the ball is in light contact between it and the end of the shaft. As the shaft revolves the ball is carried into the converging space between the end of the shaft and the race, forcing the latter against the spring which it compresses. The reaction of the spring pushes the shaft away from its position, allowing the ball to drop back to the bottom of its race. The shaft and rotating parts continue to move axially until gravity brings them back ready to repeat the above process. The only care and maintenance required by a mechanical oscillator is to keep it clean and lubricated with light oil.

Starting Up Generators

The process of starting up a generator is so simple as to need only a few remarks on some of the causes of the machine not starting properly, etc.

Before starting up a generator see that all resistance is cut in the shunt field circuit, that the oil rings are free to turn, that there is plenty of oil in the bearings, also that the brushes are bearing evenly but not too loosely or too heavily on the commutator. Then start up slowly and if everything operates properly bring up to full speed. Adjust the field rheostat slowly to the normal voltage position and throw on the load. Always use the main switches for throwing on the load, never the circuit breakers. These latter should be closed and ready for operation before the main switches are closed in order that they may open in case of a short circuit on the line or too much load connected, and thus protect the generator.

Low Voltage

Sometimes generators fail to build up full voltage upon starting up. This condition may be attributed to any of the following causes.

1—Speed too low.

2—Brushes not correctly set.

3—Loose connection or other unnecessary resistance in the shunt field circuit.

4—Part of the shunt field circuit may be short circuited, or field coils may be connected in opposition.

5—Series fields may be reversed and "bucking" the shunt fields.

6—A dead shortcircuit on the armature.

7—Voltage may be correct, but the switchboard instruments at fault.

No Voltage

No voltage may be the result of:

1—Wrong direction of rotation.

2—Reversed armature connections.

3—Broken field coil windings or connections.

4—Brushes not touching the commutator.

5—Any of the causes of low voltage as given above.

6—Loss of residual magnetism in the fields.

Compound wound machines may sometimes be made to build up by shortcircuiting the armature through the series field and in series with a piece of fuse wire of slightly less capacity than the generator. Start up the machine gradually. If the fuse wire melts, try to get the machine to build up again, or reverse the armature connections and try again. If the wire does not melt, the trouble is obviously one of the above.

Reversed Voltage

Reversed voltage is generally caused by a reversal of the residual magnetism in the fields. This is liable to occur if a compound generator is operated as a motor while shutting down with a weakened shunt field. It can be corrected by applying correct voltage to the shunt field for a few moments from an outside source.

To Reverse Direction of Rotation

If a generator is required to be driven in the opposite direction, reverse the shunt field leads and the series field leads, or reverse the armature and the commutating pole leads. This applies to generators or motors.

Paralleling Generators

To parallel a D.C. generator with others already on the line, bring it up to normal speed, adjust voltage to that of the line by means of the field rheostat, throw in equalizing switch then main switches. The proportion of the load carried by each machine can be controlled by adjustment of the shunt field rheostats. In most cases machines are not equalized for all loads and the rheostats require adjustment as the load changes in order to keep the load properly distributed.

Shutting Down Generators

In shutting down a generator, proceed as follows:

1—Reduce the load by adjusting the shunt field rheostat.

2—Open the circuit breakers.

3—Open the main switches.

4—Open the equalizing switch.

5—Shut down the engine or other driving machine.

6—Clean up machine ready for next run.

Starting Up Motors

To start constant speed motors:

1—Make sure that the lever of the starting rheostat is in the "off" position.

2—Throw in main switch.

3—Move lever arm of starting box to running position, holding it on each notch until the speed has risen as high as it will before going to the next notch.

In starting variable speed motors:

1—See that all resistance is cut out of the shunt field circuit, or that it is in the "slow" position.

2—Proceed as for constant speed motors.

3—Cut in shunt field resistance until desired speed is reached.

Shutting Down Motors

Constant speed motors should be shut down as follows:

1—Open main switch or circuit breaker.

2—See that lever arm of starting box returns to "off" position.

3—Clean up ready for next run.

For variable speed motors proceed as follows:

1—Cut out all resistance in shunt field circuit, bringing motor to "slow" speed.

2—Proceed as for constant speed motors.

(To be continued.)

HANDY RULES

By James Ellethorne

The following information may be of use to Power House readers. Printed rules describing methods for finding the contents of barrels are quite numerous. Some of them, to say the least, are unreliable, and they would not even give the approximate contents. Every engineer should know at least one fairly reliable rule of this nature. I remember the first time my employer asked me to inform him how many gallons a certain barrel would hold. At that time I did not know how to solve the problem and was compelled to confess my ignorance. I believe the following rule is fairly reliable: Find the mean diameter by adding to the head diameter two-thirds (if staves are but slightly curved, three-fifths) of the difference between the head and bung diameters, and divide by two. Multiply the square of the mean diameter by 0.7854 and the product by the height of the barrel in inches. Then divide by 231 for wine gallon, or by 277.27 for Canadian gallon.

Another handy rule to mark down is how to approximate the height of a stack or other object. Take a stake, say six feet long, and place it against the building whose height is desired. Then step back some 20 rods or more. At this point a light pole and a rule are required. The pole is raised between the eyes and the building and the rule is brought into position against the pole. Then observe the length of rule required to cover the stake at the building, and also the entire building. Divide the latter length by the former and multiply by the length of the stake in feet; the product is the approximate height of the building. For example: suppose the stake at the building is 6 feet above the ground and that one inch of the rule corresponds exactly with it. Then if the entire height of the building corresponds exactly with, say, nine inches on the rule, it would show the building to have a height of 54 feet. This is an old formula. I have endeavored to put it into a simpler form than that usually given.

The Grindle Fuel Equipment Company, Harvey, Ill., have issued their first general catalogue describing the powdered fuel equipment manufactured by them. The catalogue is very well got up, containing forty pages of reading matter and illustrations, covering the subject of powdered fuel generally as well as the equipment manufactured by the firm itself.

OUR QUESTION BOX

Questions are invited from readers regarding power plant operation and difficulties encountered

HEATING FEED WATER

Question:—How many pounds of water would be heated if the water entering the heater was 60 degrees F. and leaving the heater was 160 deg. F. and the steam was at atmospheric pressure?

Answer:—As the quantity of steam is not given, we will take the heating effect of one pound of steam. Each pound of steam in condensing from steam at atmospheric pressure to water at atmospheric pressure will give up 967 heat units, and in dropping from 212 to 160 a further 52 heat units will be given up, a total of 1,019. Each pound of water is raised from 60 to 160 degrees, therefore the heat required is 100 B. t. u. per lb. of water. Each pound of steam will therefore heat 10.19 lbs. of water from 60 to 160 degrees.

AQUA AMMONIA

Question:—What is the difference between aqua ammonia and liquid ammonia?

Answer:—Aqua ammonia is the name given to a solution of ammonia and water, aqua being a Latin word meaning water. When ammonia gas is compressed to a high pressure, and the heat of compression removed, it condenses and becomes a liquid. This is liquid ammonia, or anhydrous ammonia, meaning ammonia liquid which is entirely free of water.

Question:—What effect would oil, water, or air have on a refrigerating system, also what means is there for removing same from system?

Answer:— The effect of any foreign matter or non-condensible gases in a refrigerating machine is to decrease the capacity. Oil will cling to the surface of the coils acting as an insulator preventing the transfer of heat. Air will act in a refrigerating system in much the same way that it does in a heating system. It will occupy the space which the ammonia should occupy, and so much cooling effect is lost. The place to draw off the oil is from the bottom of the oil separator, by means of the drain valve placed there. Air and other non-condensible gases may be drawn off by the purge valve at the top of the condenser.

AIR PUMP OR BLOWER

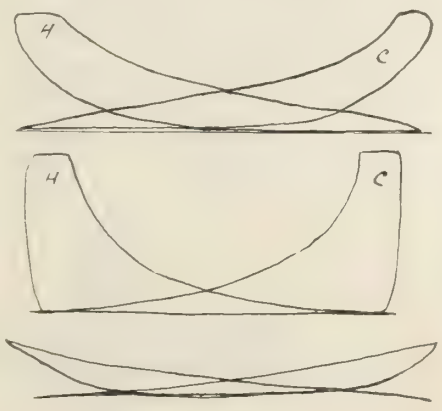
Question:— What is the difference between an air pump and an ordinary steam driven air blower?

Answer:—The term air pump is usually given to the pump used for drawing condensate and vapor from a surface condenser, or a barometric condenser. It is also applied to the pumps used in laboratory work for exhausting air from a vessel to produce a partial vacuum. The air compressor or blower takes in air at atmospheric pressure and raises it to a higher pressure, while the air pump works with atmospheric pressure as its upper limit. Both pieces of apparatus are air pumps, or air compressors, but the different duties are indicated by the term air pump or air compressor. The air pump is an air compressor because it draws in air and water vapor, or air at less than atmospheric pressure and compresses it to atmospheric pressure or slightly above so that it can be discharged against the pressure of the atmosphere. The air compressor or air blower may be termed pumps because they draw air in at atmospheric pressure, and deliver it to a closed system at a pressure of 7 to 100 atmospheres.

INDICATOR CARDS

Question:— What would good indicator cards look like from an engine running on a throttling governor, an automatic engine, and a Corliss all running on light loads?

Answer:—The following cards are actual examples from the types of engines mentioned, and submitted to us by Mr. Allen Norgrove, Chief Engineer, Le Pas Lumber Co., Le Pas, Manitoba.



Top—Card from automatic.
Centre—Card from Corliss.
Bottom—Card from throttling engine.
All on light lead.

CORLISS VALVE GEAR

Question:—Why is it not possible to set the valve of a Corliss engine to trip at more than half stroke, and still use steam economically?

Answer:—The cut off point in a Corliss gear is adjusted by means of the position of the governor rods which in turn operate the knock off cams on the valve spindle. These governor rods by being lengthened or shortened move the cam nearer or farther away from the steam hook, causing earlier or later cut off. If the valve gear is driven by one eccentric, cut off can not be made any later than half stroke for this reason. With the crank on the dead centre, the eccentric is in the centre of its stroke. When the crank reaches half stroke the eccentric is at the limit of its travel and is starting on the back stroke. If the knock off cams have not reached the steam latch by this time, it is impossible for them to do so, and the hook will not disengage, the result being that the steam valve is kept open for practically the entire stroke. Before the steam valve closes the exhaust valve opens, and the steam is blown straight through the cylinder from the steam chest to the exhaust pipe. In order to obtain a water cut off the half stroke it is necessary to have two eccentrics, so that the exhaust valves can be adjusted independently of the steam valves. By setting the steam eccentric so that the crank will have passed over the half stroke before the eccentric reaches the end of its travel cut off can be made later than a half stroke.

CONDENSATION AND RE-EVAPORATION

Question:—What is meant by condensation and re-evaporation in a steam cylinder of an engine?

Answer:—In the ordinary reciprocating engine the cylinder is being alternately exposed to steam at the initial pressure and temperature and to steam at the exhaust pressure and temperature. The steam at admission is introduced to a point where the walls of the cylinder have been subjected to the cooling action of the exhaust steam. Some of the heat of the steam is therefore absorbed in heating up the cylinder walls to the temperature of the steam, the result being that a portion of the steam is condensed. This will appear as a thin film of water on the cylinder walls. As the steam expands, it lowers in pres-

sure and temperature, until the temperature of the steam is less than that of the walls of the cylinder. This causes heat to be taken from the cylinder walls, which is absorbed in re-evaporating a portion of the moisture in the cylinder. Thus we have condensation at one point of the stroke and re-evaporation at the other. It is to avoid the losses due to this that the Uni-flow system is designed. In this engine the steam does not exhaust through the same ports as it is admitted, as in the ordinary engine. The exhaust ports are situated in the centre of the cylinder, and the piston is made long enough to cover them except at the end of the stroke. Release takes place when the piston uncovers the port, and compression occurs very early in the return stroke, so much so that in most cases provision has to be made to allow the escape of a portion of the steam when the piston reaches the initial position. In this way the admission ends of the cylinder are kept at practically a constant temperature while the exhaust always takes place in the centre and thus any sudden changes of temperature are avoided.

EFFECT OF REDUCING VALVE

Question:—What would be the effect on the steam of passing superheated, saturated, and wet steam through a reducing valve, for heating purposes?

Answer:— When steam is expanded from high pressure to low pressure without doing work, its temperature at the lower pressure will be higher than that corresponding to its pressure. In other words it will be superheated. Passing steam through a reducing valve is expanding it without performing work. If superheated steam is passed the result will be that it will have a higher superheat on the low pressure side. If wet steam is passed through a reducing valve part of the heat will be absorbed in evaporating the moisture, and the result will be that the wet steam will appear as saturated or slightly superheated steam on the low pressure side, while if the steam is saturated on the high pressure side it will be superheated on the low pressure side.

LOST MOTION ON PUMP VALVES

Question:—What is the purpose of the lost motion on the steam valve of a duplex pump?

Answer:—Take the position of the valves when the two driving levers are vertical, and the valves in mid-position which is the correct one. The valves are just covering the ports, and there is enough slack on the check nuts or lugs of the valves in themselves to allow them to crack the port on either end. Now take a bar and move one rod to the end of its stroke. We have moved the valve on the opposite cylinder to the end of its stroke, leaving it open for steam and it will in turn move to the end of stroke at the same time opening the first valve to give steam to the position first moved. and causing it to return. If there were no slack on the valves the rods would come in mid position again at the same time, and the valves would cover the ports on both cylinders at the same instant, the result being that the pump would stop. Owing to the fact that at the commencement of the stroke the pump rod must move sufficiently to take up the slack in the valve spindle before it moves the opposite rod, the two rods never pass the centre at the same time one always being in advance of the other and thus there is no dead centre. This same factor ensures the valve remaining open to steam until the piston has completed its stroke.

STEAM GAUGES

By J. E. N.

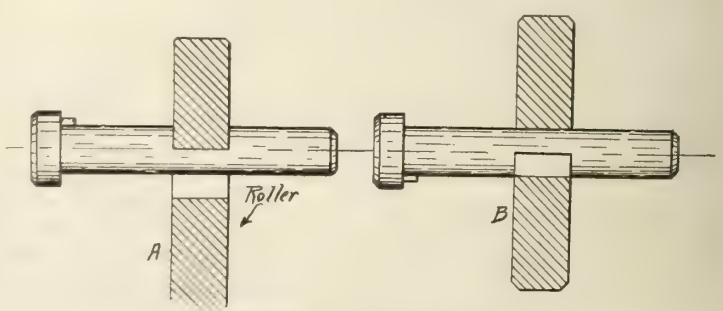
There are a large number of perfectly good steam gauges discarded, especially in small out of the way plants in country districts, cheese factories, etc. Many of these plants have good men in charge, men who understand and carry out their work quite as regularly and capably as the man in the large city plant, perhaps better in some cases. When the law permits it, some of these small plant owners have them operated at as low a labor cost as possible. This may mean that a cheap, indifferent operator is in charge. Such a man usually discards a gauge when it registers high or low, or if the hand checks at any point, that is, if he does anything in the matter at all. He tells his employer it is beyond repair and to get him a new one. The old one is discarded without examination. The methods of cheap, inexperienced power house help are usually costly to the owner. Probably the old gauge is as good as the new one. Sometimes a little dirt gets inside the casing and lodges in the small gear teeth, or, perhaps some time in the past a thin oil has been placed on the mechanism and become gummed with the heat and dust. Washing the mechanism in gasolene and allowing it to dry in a clean atmosphere will prove a cure in either case. When cleaning the mechanism of a steam gauge no oil heavier than coal oil should be used and it is better to wash it off with gasoline, as the coal oil can, and sometimes does, collect enough heavy dust to affect the operation. The mechanism is very delicate and little is required to interfere with its proper operation. If a man has not the skill or knowledge to do repairs it is not costly, and it is safer to have an experienced outside man do it. I have seen a man using a fairly rough file and a heavy pair of pliers in an attempt to repair a gauge. Often a gauge will register correctly up to a certain point and neither cleaning or setting the indicating hand makes any improvement. Several things may be wrong. It may be caused by lost motion due to wear, perhaps there is a very small leak in the spring, or the spring has hardened or softened. The average engineer can not remedy these defects.

The Pacific Meat Co., 268 Columbia St., Vancouver, B.C., is considering the erection of abattoir and cold storage plant which will cost around $100,000.

WHY THE EXHAUST VALVE DID NOT WORK

By G. Blake

The writer, whilst working in a general repair shop some years ago, was one day sent out by the foreman to examine a gas engine in a bakery, the complaint was that it pulled up when the load was on. The engine was of a very old type, but it seemed to be in good working order as far as the writer could ascertain, the pulling up with the load on indicating that some part was not functioning properly. When the engine was running it was noted that the small cam roller, which actuated the exhaust valve mechanism, appeared to have a very small amount of lift, the engine was accordingly shut down and the roller examined and it was discovered that the pin on which the roller worked had become worn on the top side, that is the side on which the thrust took place when raising the valve to exhaust the exploded gases. This pin was worn practically half way through, see sketch A, consequently the valve did not open sufficiently to allow the gases to escape, which would account for the pulling up when the load was on. The old pin was turned half way round so as to present the unworn part to the bore of the roller, see sketch B, thus giving the valve nearly the proper amount of lift. This of course was only a temporary adjustment until a new pin could be made. The engine pulled all right on lead after this simple alteration.

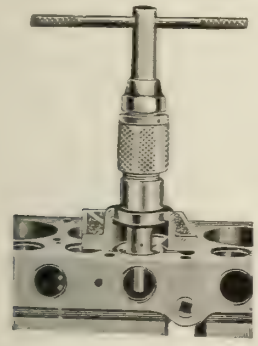


Why the exhaust valve did not work.

Progress in New Equipment

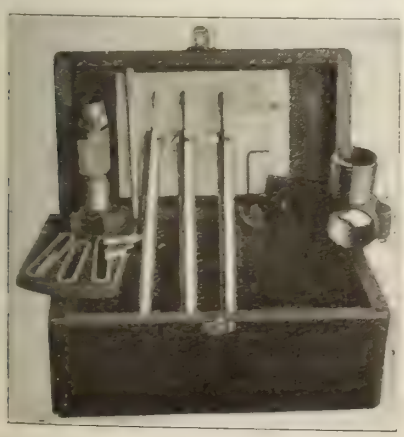
VALVE RESEATER

A very important factor in the overhauling of motors and pumps is to see that the valves seat properly and to do this they must be in perfect alignment with the valve guides. A device for performing this has just been placed on the market. This appliance does not depend on the small pilot end to guide the cutter, but the latter is guided by a large accurately ground bearing above the valve seat. A screw feed is provided and the tool is held steadily to the work, and no digging in or chatter takes place. When refacing valve seats top and bevel are both faced so that a narrow and effective seat is always presented to the valve, thus aiding in expelling the carbon. Cutters are made of high speed



Valve reseating tool.

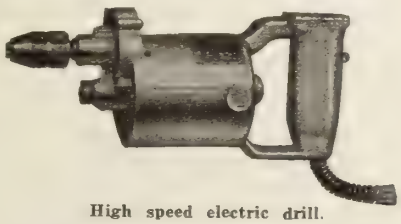
steel and shop and garage men can resharpen and keep them in shape. The set consists of three boring bars, with 5/16in., ⅜in. and 7/16in. pilots; two valve seating cutters, 45 deg. angle; one knurled handle; two boring cutters and wrench. All incased in mahogany finished chest. Weight, 18 lbs. It is manufactured by the Hinckley Machine Works, Hinckley, Ill.



Valve reseating and boring set in mahogany case.

SMALL ELECTRIC DRILL

A small but highly serviceable electric drill has just been offered to the trade. It is extremely compact and has remarkable strength for drilling ¼in. holes in steel. It weighs only four pounds and can be supplied with either 110 or 220 volts motor, suited for direct or alternating current. It is amply provided with oiling and ventilating facilities, and is fitted with bronze bushings and



High speed electric drill.

gears. The drill can be held and operated with one hand, and chuck and drill are always in view of operator. The Lovejoy Tool Works, Chicago, Ill., are the makers.

LIGHT OR HEAVY OIL

By James E. Noble

I thought I was a "wise one" where lubricating oil for steam engine is concerned, but I was told a thing or two a short time ago by a fellow, that has taken some of the conceit out of me. I had been doctoring a boiler feed pump which was making a disagreeable noise, when it was running. I tried several things without success, loosened up the packing on the water plungers, etc., but with no verdict of cured as a result. Well, the fellow in question advised me to use a lighter oil, but with a high flash test. I am always willing to try out a thing once if it looks reasonably safe, so I tried out his suggestion and the noise quit. I went back to the heavy oil and the noise, which was a sort of groaning one, started again; a return to the light oil made a permanent cure. I remember talking with a man who had this same idea; he also claimed that less of this kind of oil could be used than a thick oil, with better results. Of course, a thin, low flash test oil, would be no good, although I know a would-be inspector who advises his engineer friends to use a thin low flash test oil so that it will vaporize in the cylinder and thus oil the walls. Of course he is making a mistake, as such an oil would practically all pass out with the exhaust steam without doing any good.

USING WASTE STEAM

With coal at its present high cost and a shortage in the near future possible, any idea which will tend towards a saving should be welcome. Hundreds of steam plants shut down every Saturday at noon, others do so the day preceding every holiday. In many of these plants the fire is allowed to die out along with the steam pressure in the boilers. This is especially the case during the summer months, the fire not being re-started until early Monday morning. Surely, in most cases, some plan could be arranged so that all the steam possible to take out of the boiler or boilers could be used for some purpose, be it drying, boiling or otherwise, with the partly burned fires allowed to do their utmost, by throwing the dampers open, and using the large amount of stored heat in the boiler water, settings, etc. The quantity of heat available would be considerable. It seems a pity that all this steam is wasted when a bit of thought might devise some plan to save it. I remember hearing or reading about one man who secured from 2 to 8 hours drying oven service from such steam formerly wasted. I believe if engineers in plants should draw their employers' attention to plans of this nature their interest in the plant and its possibilities would be welcomed by the owner.

BULLETINS

We have received from the Atlas Valve Co., a handbook on reducing valves, which they state is the result of their fifteen years experience in the manufacture of this line. The book contains a large number of charts and formulae connected with the flow of steam through pipes, and the question of using the right size of reducing valve for job in hand clearly explained.

The Barber Greene Co., Aurora, Ill., have sent us their bulletin describing their U Belt Loader for reclaiming coal from storage or unloading from cars to storage. This is a portable conveyor, having the added feature of being self propelling, so that there is no labour needed to move it from one place to another. Accompanying the bulletin is a data sheet containing more detailed information.

Lethbridge, Alta.—A school to cost $50,000 for Saskatchewan S.D. No. 1,036, and Albert S.D. No. 1,753, will soon be erected if present plans go through. A. M. Jeffers, architect, 210 McLeod Bldg., Edmonton, is preparing the layout.

The Operators' Point of View

PLASTIC CEMENT

By C. F. Pye

I have increased my boiler efficiency fifty per cent., and one of the most effective things done to obtain such efficiency was to fill all the cracks in the boiler setting with plastic cement, and where the cracks were very large, or a brick was left out, the hole was filled with a thick mixture of plastic cement and mineral wool.

All cracks, such as the outlines of iron work, such as clean-out door and boiler front were well filled with plastic cement. The holes in the settings where the blow down, blow off, feed pipes etc., where they enter the settings were filled with a very thick mixture so that the heat will not soften the cement before it sets.

After this was done, I noticed that I had a much better draft, which meant better combustion and cleaner flues.

Then one day my arch over the fire doors fell down, and left a hole large enough to let a brick fall through on its flat side. This being a very busy day I could not keep up steam, so I tried plastic cement and mineral wool in the following manner: I cleaned all the remaining brick of their soot and ashes, and with an old paint brush I painted the cleaned brick all around the hole, this making a good adhesive surface for the patch. Then I laid a piece of stiff asbestos paper across the hole, and applied a one inch coat of loose mineral wool over the paper, then a very thick mixture of plastic cement and mineral wool.

The heat then softened the binder and allowed the free mineral wool that was applied on the paper, to become saturated with a good binder, that when later dries, and makes a splendid bridge and protecting the top part of the patch, which remains soft and pliable, and remains air tight.

A patch of this description has been in service for about five months and is in good condition; thus saving a cut-out boiler with all the involved losses; the losing of steam when most needed, and the price of a new arch, for at least until it could be conveniently replaced, and with no greater cost than one dollar in material, and half an hour in labor.

Similar repairs have been made when the fire has destroyed the brick, and they all hold good.

Another splendid place for it is in the V-shape, that is, where the boiler shell meets the setting.

When repairing or building, the space ought to be filled a few inches with loose mineral wool then a coat of thick mixture of mineral wool and plastic cement. Then, as before, the cement gives off some of its oil, and causes the loose wool to bind tegether, protecting the top from the heat and allows the top part to adhere to the boiler on one side, and the setting of the other, thus making an air-tight joint, and allowing the boiler to expand freely.

This soft cement on top will catch any small, loose particles of mortar or brick that are always dropping off in the place mentioned, and prevent them from falling down in the bottom of the V-shape when the boiler is cooled, and causing the wall to be pushed further apart at the next heating.

The V-shape may be filled with a coat of cement, and a coat of dry wool alternately, each an inch thick for about seven inches. Then you can enjoy a good-looking boiler, setting free from cracks.

You can apply this mixture to the rear end where the setting meets the boiler above the flues in the combustion chamber.

This has caused me much trouble, and the company much fuel.

SHORT CUTS FOR ENGINEERS

The Editor,
The Power House.

The writer has had brought to his attention an advertisement for a set of engineering books recently placed on the market. The advertisement in question gives the following which purports to be an extract from one of the books:

"Why spend a ridiculous amount of time figuring horse power by this method (the method they all use)?

Rule: Multiply twice the mean effective pressure in pounds per square inch by length of stroke in feet, by area of piston in square inches and by number of revolutions per minute: divide this product by 33,000.

Firemen, Engineers and even professors waste time and mental effort with this out of date rule—Why not do it thus:

Rule 2: Multiply the decimal .000004 by diameter of piston in inches squared, by stroke in inches, by number of revolutions per minute and by mean effective pressure in pounds per square inch.

Either of the above rules give results accurate enough for practical purposes, and if anyone were making calculations of the horse power of different sized engines under different conditions every day or so, the second rule might save a little time.

The average operating engineer does not figure horse power more than once or twice a year or so, or if oftener it is generally the same engine over again for which he can calculate his own cylinders constant. With infrequent use as above such a rule as above would be forgotten between times of use, and unless a man has his book in his pocket he would likely be stuck for figuring horsepower, as no engineer can afford to cram his memory full of rules which he is not going to use more than once or twice a year.

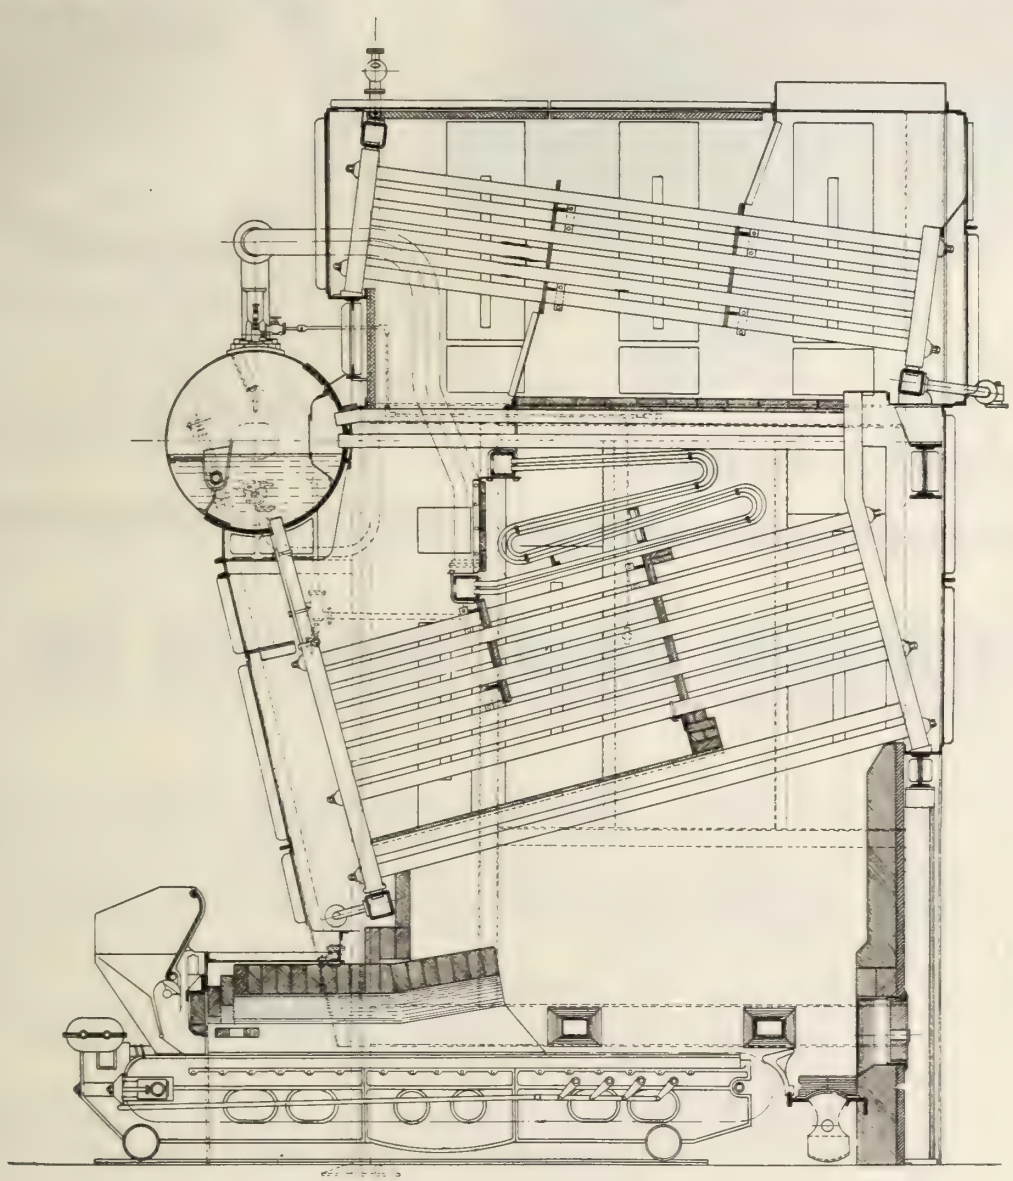
Any good textbook or hand book should give and explain the derivation of Rule No. 1 as given above, as that formula is derived from first principles. If any engineer once goes over this it is merely a matter of using a little common sense to develop the rule again without the use of books at any time without any tax on the memory. It seems to the writer, therefore, that such short-cuts as above should be discouraged, because their development from first principles is more complicated, and most people's memories fail at times, also most people do not carry textbooks on the job with them, so that when the time comes to use the shortcut, it can not be used.

The writer is not trying to knock the particular set of books referred to, but would like to impress on engineers the value of getting their knowledge from first principles and thus be able to develop formulas when needed instead of trying to remember a lot of facts and figures of which they do not know the full meaning.

Yours etc.
M. B. WATSON

The American Well Works, Aurora, Ill., have sent us Bulletins 130, 156, 157, 158, 159, and 160, dealing with their various lines of pumps for well purposes. The apparatus covered includes deep, well cylinders and accessories, deep well turbines, deep well power heads, deep well steam pumping engines, open impeller centrifugal pumps, double suction centrifugal pumps. Each bulletin describes and illustrates the particular apparatus named.

High Efficiency Boilers



(Cut lent by courtesy of Eng. Institute of Canada.)

MARINE BOILER---ADAPTED FOR LAND PURPOSES---EQUIPPED WITH CHAIN GRATE STOKER, SUPERHEATER and SUPERPOSED ECONOMIZER

The construction embodies the same well-known principles as the standard type; freedom of circulation and economy when forcing being important factors of both designs. It has the added advantage that a large amount of boiler horse-power occupies a relatively small floor space.

This type is particularly useful for central stations and other plants where turbines are used and the working pressure is high. It operates economically under the special conditions of variable loads with heavy peaks. A big increase in efficiency over smaller boilers is effected through a reduction of radiation and other losses.

The individual Economiser superposed on this boiler increases the efficiency, reduces the flue gas temperature and effects considerable saving in space and of many of the losses incident to the use of separate economisers

BABCOCK & WILCOX, LIMITED

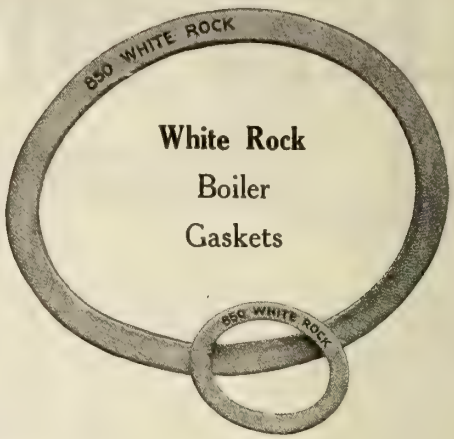
Toronto Office: Bank of Hamilton Building.

Raybestos Jointing



Raybestos Gaskets

No Engine Room Test Can Be Too

ENGINE efficiency can only be maintained economically with good Packings. Power absorbed in the Stuffing Box is reflected in waste of coal. And such waste soon runs into more money than it would cost to get real efficiency by the use of highest-grade packings.

What **is** high grade packing?

The important features of a truly effective packing are **heat resistance** and **long wear.**

These two qualities are dependent upon the use of Asbestos as the basic ingredient—preferably that long-fibre, silky asbestos which is mined at Thetford.

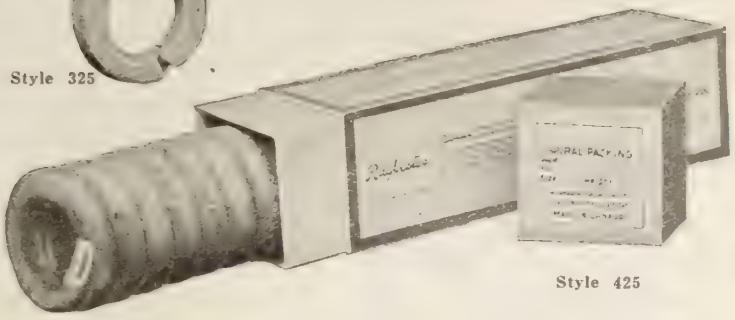
This superior Canadian Asbestos, when treated by Raybestos methods—and marketed under the Raybestos trade-mark, becomes a product which can be relied upon for service under any and all conditions, and for all kinds of power transmission.

The Canadian Raybestos Company

Raybestos

Sold by MINE, MILL and

Style 325



Style 425

Raybestos TWIST

Style 550

for small piston rods and valve stems

Raybestos

Spiral and Ring Packing

Made in all sizes

Severe for These Better Packings

From the Sunny South to the Frozen North, under the sea and overhead, you will find Raybestos Packings giving service.

Wherever Power is transmitted—wherever gas, steam and liquids are controlled by pressure or conveyed within unnatural bounds—Raybestos Packings find a duty.

Wherever heat is the highest and pressure the strongest, they stand the gaff.

The line is complete. There is Raybestos Jointing, for all flange joints; Raybestos Twist for Valve Stem and Piston Rods; Raybestos Discs for Valves; Raybestos Gaskets for Boiler Manholes and Handholes; Raybestos Spiral and Ring Packings for all types of Pumps and Engines.

Many packings are entitled to the description "good packings"—Raybestos Packings are **better.** And the harder the test, the higher the heat, the more extreme the pressure, **the more completely their superiority reveals itself.**

A Striking Message

A STRIKING message to manufacturers of power-house equipment is derived from a letter written by a "Power House" reader in reply to a request for a criticism of the paper and for suggestions as to how it could be improved. Here is the letter:

"I believe Power House compares favorably with other power-house journals in many respects. One department I would like to see at least three times its present size is the selling section. Many of the ads. are from all-American U.S. firms but there must be many others, some of them with Canadian branches and agencies, who do not carry an advertisement in Power House. **This is a mistake on their part**, but for all I know to the contrary [illegible] of interest on [illegible] Power House ad. managers in getting after them. **It is an absolute fact that the engineer is more than ever dependent upon his technical journals for information in connection with new ideas in power plant equipment. He does not depend upon the reading pages SO MUCH AS ON THE ADVERTISEMENT PAGES.**"

SITUATIONS WANTED

ENGINEER—HOLDING ONTARIO CERTIFICATE, thoroughly experienced in refrigeration and electricity is open for position. Box 17821 Power House, Toronto. P. 4. H.

WANTED—SITUATION AS GAS ENGINEER for producer or city gas, gasoline or kerosene engine. Preferably for small electric light plant, able to do own repairs, climb poles and do own wiring and take full charge. Apply Box 31821, Power House. p.2.h.

EXPERIENCED MACHINIST WITH ENGINeer's certificate, good at general repair work desires position. Apply Box 14921 Power House P2H

T. H. FENNER'S SPECIAL CORRESPONDence Course for First, Second and Third Grade certificates. Covers all requirements of the Ontario Board of Stationary Engineers. For terms and particulars write T. H. Fenner, Apt. 16, 311 Kendal Avenue, Toronto.

STATIONARY ENGINEER—SECOND CLASS. requires position, ten years' experience of steam generation, refrigeration, cold storage and electric generation, thoroughly experienced with heating systems and hydraulics and all classes of stationary engines, used to large plants, good references. Apply to Box 5122. P.3H.

DIE SINKER — THOROUGHLY PROFICIENT in all kinds of first class work. Apply Box 107, Power House. PFH

AGENTS WANTED—ONE OF THE LARGEST manufacturers of steam jet ash conveyors in the country desires representation in Canada. Only those calling on Power plants daily, and thoroughly familiar with this line of equipment need apply. Liberal Commissions. Apply Box 106, Power House. Toronto. P.F.H.

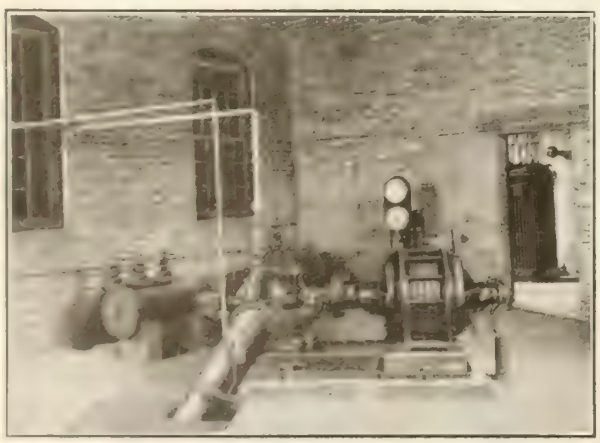
To Obtain Maximum Benefits From High Power Factor and High Efficiency Install

DE LAVAL MOTOR DRIVEN CENTRIFUGAL PUMPS

THE power factor of induction motors drops off rapidly at fractional loads. With ordinary centrifugal pumps it is customary to purchase motors having considerable extra capacity to take care of overloads imposed when the pumps are operating at capacities in excess of the normal rating. This means that when operating at the normal rating and reduced capacity on the motor the power factor is low.

A De Laval centrifugal pump does not overload a constant speed motor when the capacities are increased considerably, as is the case with ordinary centrifugal pumps and consequently the capacity of the motor can be selected to correspond to the power required at the normal capacity where the power factor would be the maximum.



Ten-inch motor driven De Laval centrifugal pump in the water works plant at Sydney, Nova Scotia; 3,000 gal. per min. against [illegible] ft. head

De Laval centrifugal pumps have the highest efficiencies, maintain these efficiencies over wide variations of load, due to the type of casing and diffusion means employed, and have a power limiting characteristic such that under no conditions of load or pressure will a pump require more power from the motor than is required at the point of best efficiency.

The De Laval centrifugal pump requires only a small starting torque, which permits the use of synchronous motors for correcting power factor where desired.

We will be glad to give you references to numerous installations of De Laval motor driven centrifugal pumps in leading Canadian cities and industrial establishments.

Ask for special publication B-100.

HINTS TO BUYERS

Kingsbury Thrust Bearings

Made in Canada

Our pivoted-block Thrust Bearings are a complete solution of all thrust-bearing problems in hydro-electric units, steam turbines, ships' propeller shafts, centrifugal pumps, and similar work involving heavy loads and high or low speed.

Maximum Durability and Reliability.
Lowest possible Friction.
No limit to loads or speeds.
Protected by numerous Canadian Patents. Complete manufacturing facilities in Canada, insuring prompt deliveries and service.
Send for Catalogue.

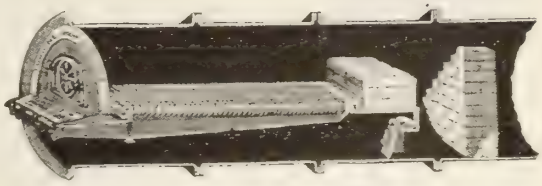
THE TURBINE FURNACE



Can you do this ---on Coke?

AT THE plant of P. Burns & Co., Vancouver, a Turbine (Patent) Furnace under a No. 3 Boiler maintained 7 lbs. of steam per lb. of COKE DUST at 212° F.

The Turbine is a fuel-money-saving Furnace for externally or internally fired boilers. Burns coal slack, coke dust and low grade fuel with all the advantages of a forced draft. **Shall we send you particulars?**

Agent for Canada

PERCY A. GOEPEL
525 Pender St. W., Vancouver, B. C.

FUEL SAVERS
Vulcan Soot Cleaners

With a Vulcan Cleaner installed, the tubes in a boiler are **cleaned right** and as many times as necessary in a day.
The efficiency of the boiler is improved. The capacity is increased.

The Genuine SPENCER Damper Regulator

Recognized as the best for the last 35 years.

628-630 ST. PAUL ST. WEST
MONTREAL

PLIBRICO
JOINTLESS

FURNACE LINING

PLIBRICO is a plastic refractory. When molded into jointless baffles, side walls, and arches, and properly baked and vitrified, it forms boiler settings that resist heat up to 3100°F., that are air and gas tight, and that outlast laid-up fire brick many times.

When the first container of PLIBRICO is rolled into a plant, profits increase, for PLIBRICO means a saving of more than 10% on fuel bills; it is a time saver and a labor saver, and it is an insurance against loss from shutdowns for boiler setting repairs.

Get acquainted with PLIBRICO. Our book L-63 on "Modern Furnace Building," gives full information. Yours for the asking.

PLIBRICO is delivered only in steel containers of distinctive appearance, as shown below.

DISTRIBUTORS: Beveridge Supply Co., Ltd., Montreal, Que.; Shell Bar Boico Supply Co., Ltd., Toronto, Ont.; Evans, Coleman & Evans, Vancouver, B.C.; Winnipeg Supply & Fuel Co., Winnipeg, Man.; Gorman's Ltd., Calgary, Alta.

At Provincial Paper Mills

IN the plant of the Provincial Paper Mills at Mille Roches, Ontario, described in a leading article in this issue, Bailey Fluid Meters are measuring the steam in their distribution lines.

Bailey Meters are being used in practically all large paper mills in Canada for guiding the firemen in operating their boilers efficiently, checking up the steam consumption by the various departments, such as paper machines, wrapping machines, prime movers and heating systems, also for measuring water supplied different departments and boiler feed. The same type of meter is equally adaptable for the measurement of steam or water.

It is notable that one company controlling the amount of steam used in its digesters by Bailey Fluid Meters, and guiding the cook from the record on the chart, uses less steam per pound of pulp than any other concern, also assuring itself of a uniform product from day to day.

As these meters are now being manufactured in Montreal, prompt delivery is assured our customers and a staff of Mechanical Engineers is maintained here to give adequate service with our equipment.

"Sirocco" Products for Mechanical Draft

Only through the use of mechanical draft and stokers is it possible to maintain the high rates of combustion necessary to carry the peak loads in modern power plants. The blower is the most important auxiliary upon which the uninterrupted and efficient operation of the boiler plant depends.

The blower, best suited for any mechanical draft installation, depends upon many factors—the kind of fuel, the boiler rating, the type of stoking, the method of drive, whether electric or steam, and numerous others. The blower is just as necessary to the power plant as lungs are to the human body.

Operating continuously, the fans must be of rugged, substantial construction.

"Sirocco" Fans are so built that dependable, never-failing service is a certainty. "Sirocco" Products afford a selection of apparatus to most efficiently meet my condition.

Our engineers will be glad to make recommendations covering your particular requirements.

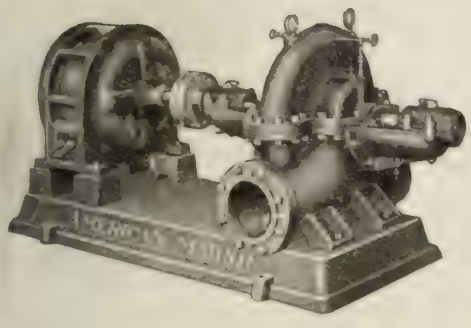
AMERICAN-MARSH PUMPS

Centrifugal and Direct Acting



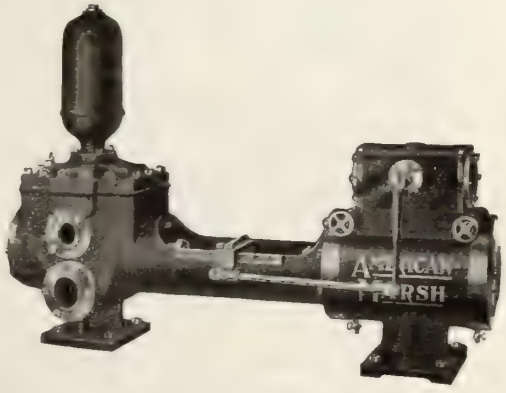
Designed for use in power plants where absolute reliability and high efficiency are essential. For over thirty-five years American-Marsh Pumps have been recognized as standard throughout the Dominion. There are over 160,000 in successful operation.

The sturdy rugged construction and heavy cast bronze fittings insure long life and a minimum repair expense.

American-Marsh Centrifugal Pumps are built with the same painstaking care that characterizes the construction of the direct acting line.

The line includes:

Boiler Feed Pumps	Jet Condensers
Air Compressors	Vacuum Pumps
Deep Well Engines	Condensation Pumps
Centrifugal Pumps	Sump Pumps



May we send you our general catalog?

Better Protection For Engine or Transformer

The De Laval Oil Purifier insures your engines or transformers against damage resulting from keeping inefficient oil in service. Continued use of the De Laval maintains the original characteristics of the oil so that it may be used indefinitely. Thus a saving of oil is made which will in a short time pay for the Purifier.

De Laval Oil Purifiers

are furnished as stationary units to be connected into the turbine or Diesel lubricating system, or piped up to transformers. A portable transformer oil purifier is furnished for the sub-station service. This portable unit may also be used for cleaning up batches of lubricating oil.

De Laval Oil Purifiers are made in sizes to fit every plant. **Write for Bulletin No. 105, which tells how they will save money for you.**

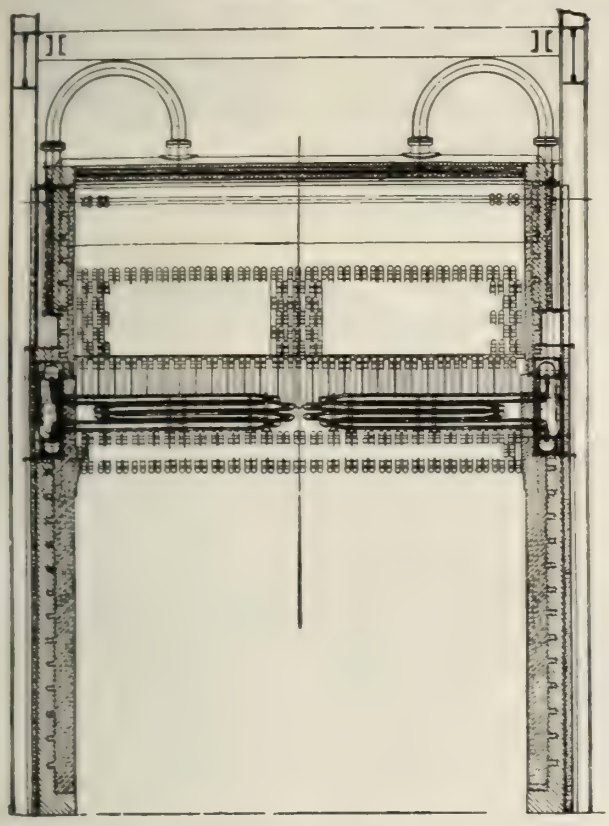
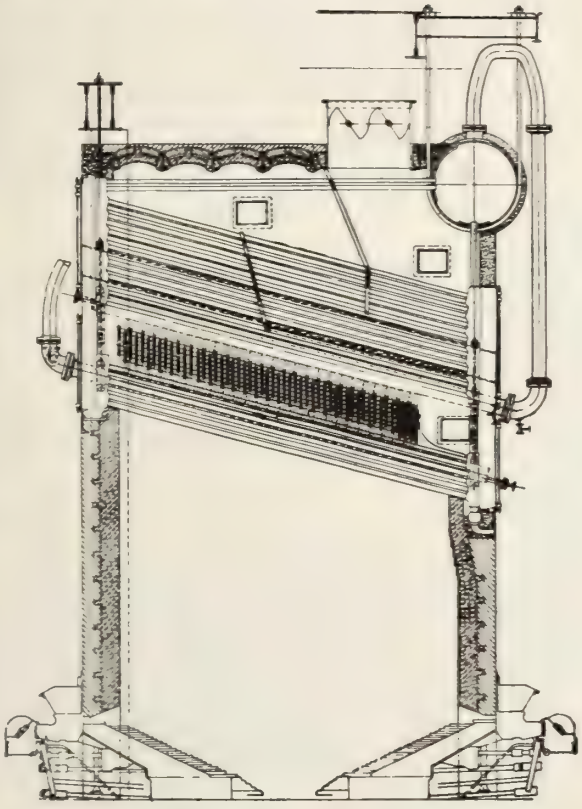
ELESCO

SUPERHEATERS





An Important Advance in Superheater Engineering

The important features embodied in the design of the ELESCO Superheaters in the 12-1890 H.P. Boilers at the Hell Gate Plant of the United Electric Light and Power Company, New York City, may be briefly summarized:

200° F. superheat at a low first cost.
Safe gas temperature zone location.
Minimum fluctuation in steam temperature at different boiler ratings.
High steam velocities with minimum pressure drop.
Equal distribution of steam through the superheater at all ratings.
Breaking up of possible slugs of water.
Fewest possible number of steam tight joints.
Elimination of baffle joints between superheater and boiler.

The performance of the ELESCO Superheaters in this plant fulfills the exacting requirements of a central station of large capacity.

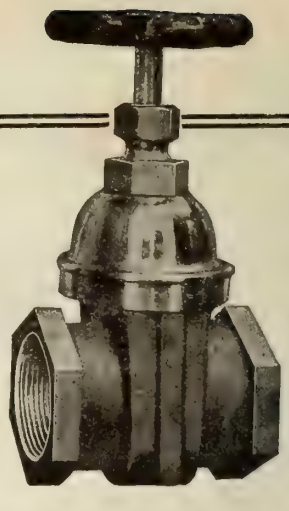
MADE IN CANADA

Imitated since 1885—but "Quality Tells"



THIS is our genuine Weber Gate Valve as manufactured by us since patented by Mr. Weber over 40 years ago. Many manufacturers have exploited imitations depending upon a "lower cost" appeal but the superiority of our Original Weber Gate Valve has continued to assert itself. For over thirty-five years many of the largest distributors of valves have sold and are still selling KERR "Genuine Weber Pattern Gate Valves" and recommending them as the only reliable. This degree of confidence is the result of our maintaining the original standard of product as regards material and workmanship.

All our goods are thoroughly tested before leaving our works and every sale of KERR products is backed by a KERR guarantee.

Garlock Style No. 987
HYDRAULIC DUO PACKING

A combination of rubber cushion and waterproof hydraulic rings. This packing gives excellent service for medium pressures. The reversed cushions make it very effective in handling sandy water, receiving constant lubrication from the waterproof hydraulic rings.

Garlock Hydraulic Duo Packings have been prepared with a thorough understanding of the diverse conditions of hydraulic service.

Among our combinations we have a packing that will solve your problem and succeed where other hydraulic packings have failed. Let us advise you.

Morrison SteamGoods

TRADE MARK J.M.T. REGISTERED A GUARANTEE OF QUALITY

Products of Service

THE most valuable asset that any business concern can establish is Confidence and Good Will.

Steam Specialties, perhaps more so than any other commodity, stand or fall upon their reputation for absolute and unvarying quality.

The Confidence and Good Will built up by the Morrison line is a natural sequence of a conscientious effort to apply, to their manufacture, the skill and knowledge secured by over sixty years' experience.

So while this asset is a natural product of service, it stands equally as an essential for the continued security of users of the Morrison line.

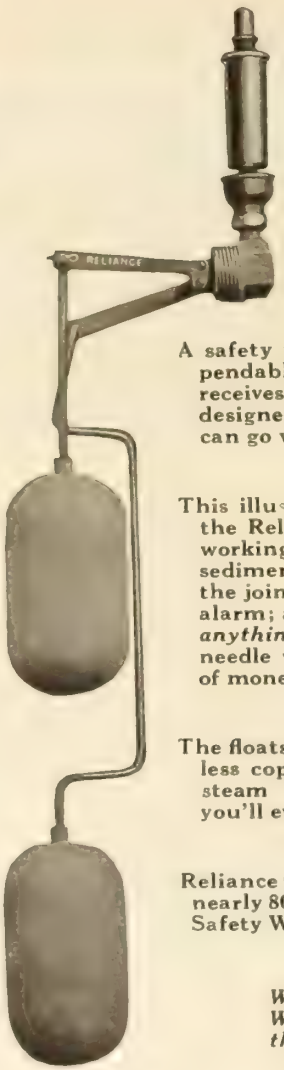
positive warning that the water in your boilers has reached a dangerous level



THE warning may be given by a single whistle, by a whistle for each alarm, by a whistle and an electric signal, or by an electric signal alone — whatever your plant requires.

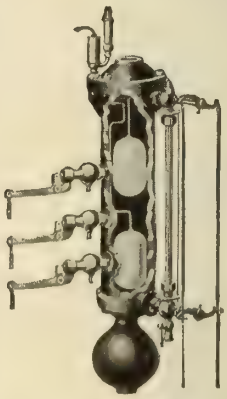
A safety water column must be absolutely dependable—*ALL* the time. Even though it receives only perfunctory care, it must be so designed and built that practically nothing can go wrong with it.

This illustration shows the vital mechanism of the Reliance high and low water alarm. All working parts are up out of the water; no sediment or foreign deposits can clog or stiffen the joints. There is a separate float for each alarm; and the low alarm float is so set that if *anything* happens to it the whistle blows. The needle valve which the levers operate is made of monel metal—you know what that means.

The floats are Reliance made of reinforced seamless copper, and every one factory tested to steam and water pressures far higher than you'll ever subject them.

Reliance Columns *are* dependable. The fact that nearly 80% of all the columns in use are Reliance Safety Water Columns is considerable evidence.

Write to us for full information. We are preparing a new catalog that will be ready soon.



Here is the complete column cut away to show the float mechanism. The cost of this safety device is so low and its service so important, that no boiler plant — one boiler or fifty—can afford to be without it.

Files Hand Stokers Getting Results

PANTHER RUBBER COMPANY, LIMITED

GENERAL OFFICES AND FACTORIES
SHERBROOKE, QUE.

SHERBROOKE, CANADA September 23, 1921.

The Waterous Engine Works Co. Ltd.,
Brantford, Ont.

Gentlemen:

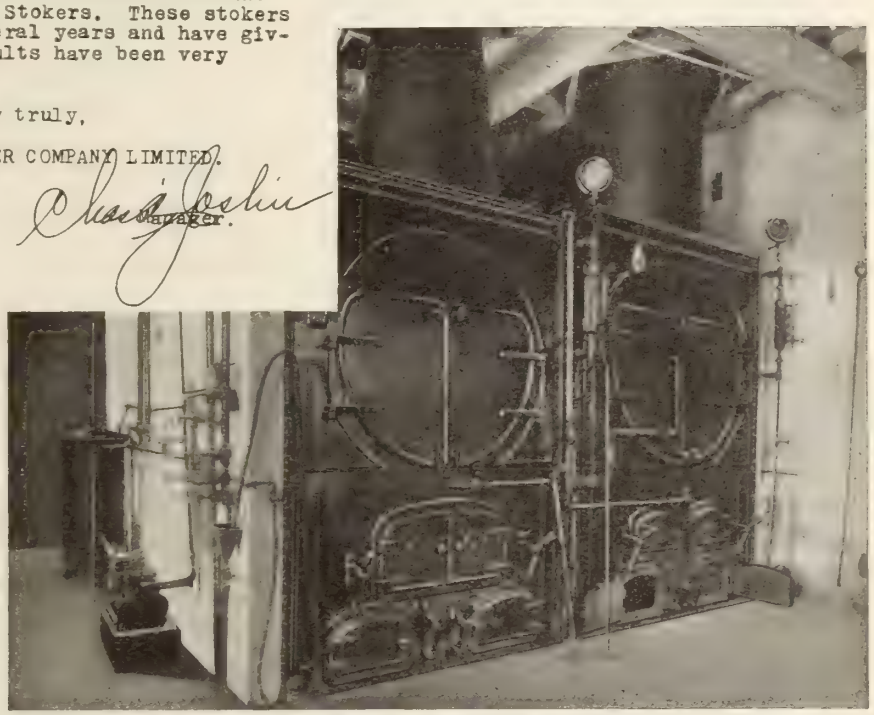
In reply to your letter of the 8th instant we have in our plant the Files Stokers. These stokers have been in operation for several years and have given excellent service. The results have been very satisfactory.

Yours very truly,

PANTHER RUBBER COMPANY LIMITED.

Manager.

CAJ/RMK



It is the uniform excellent service and general satisfaction that have caused progressive men to select **Files Stokers.** These are typical of the more complete data we have compiled:

One installation (3,600 H.P.) saved enough coal to pay for their stoker investment in five months.

A Files installation operated for five months continuously at an average rating of 223%—doubling their steam output.

Files stokers increased efficiency of one plant sufficiently high to warrant discontinuance of two out of eight boilers.

Here is a ready explanation of these achievements:—

1. **Complete volatilization of green coal, causing intensified combustion and smoke dissemination.**
2. **Correct distribution and proper proportion of air according to load carried.**
3. **Fuel bed continuously kept clean, uniform and rich.**

Given the opportunity we will be glad to present these facts for your complete satisfaction.

The Waterous Engine Works Company, Ltd.

Brantford, Ontario

The Safe and Certain Boiler Cleanser

PUT a barrel of BOICO in your boiler room. It's the most efficient and economical **clean-boiler insurance** you can adopt. BOICO routs the most stubborn cases of boiler scale formations quickly and thoroughly.

Hundreds of Plants are Using BOICO Every Day With Unqualified Success

What BOICO will do in one plant it will do in another—**it will do in yours.** BOICO loosens and brings away the hardest of old formations and keeps new scale from gathering. Yet it never does the slightest injury to boilers, valves or packings. Neither does it carry over in the steam, nor cause foaming or priming.

We are confident that BOICO will live up to all our claims and are prepared to let you test it FREE of cost. You have nothing to lose by trying it—let us hear from you.

Anti-Clinker Shell Bar Grates

There's no coal waste where these grates are used. Maximum air-space provides for perfect combustion. No clinker formation here, and you get more heat with less fuel.

One-Piece Jointless Furnace Lining

Why shift the blame on your engineer or fireman when it is your furnaces that are not up to the highest point of efficiency? USE PLIBRICO—it lasts longer than fire brick and is easier to instal.

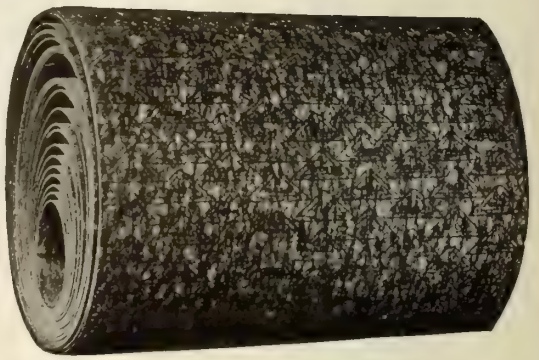
Tip-It Patent Welding Process

With TIP-IT you get tools with shanks of carbon and tips of high-speed steel.

Shell-Bar Boico Supply, Limited 1-15 Saunders Ave., **Toronto**

Sales Agents: Mill Supply Department, Beveridge Supply Co., Ltd., Montreal; Adolphe Huot Reg'd., Quebec; Adam Davis, Cobalt, Ont.

For Tight Joints



Durabla compressed asbestos fibre sheet packing makes tight joints on steam, water, air, oil, ammonia and acids at all temperatures and pressures. Joints can be broken without injury to gaskets. It will not burn out, blow out, pulp at the joints; requires no following up and is not affected by vibration or condensation. Durabla Packing meets all conditions of shipping and storage.

Made in Canada by Canadian Durabla, Limited

and sold on a service basis by

Fisher Steam Trap (Type 33)

How to Cut Your Replacement Costs

When you are making repairs to your heating system you should ask yourself several questions—

"How long has this device been in operation?"
"Has it performed satisfactorily?"
"Has it required excessive repairs?"

If these questions are not answered favorably you should immediately install devices that will answer these questions satisfactorily next year and every year for years to come.

Fisher Steam Specialties have earned a reputation for long life, accuracy and economical operation. Engineers throughout the country rely on Fisher Specialties to help cut replacement costs.

FISHER STEAM TRAP
(Type 33)

will keep your steam lines absolutely free of all condensation. It insures your steam reaching its goal dry and hot. Extra large capacity — positive dumping action—monel metal valve and seat — permanent water seal against steam leakage.

FISHER REDUCING VALVE
(Type 10)

is a double-seated, positive acting valve. Sensitive—accurate — long-lasting—cannot hammer or stick. It can be equipped with different sizes of diaphragm to render exactly the service you require.

FISHER REDUCING VALVE
(Type 11-A)

is like Type 10, but built with expanded outlet which makes it possible to effect great economy in installation costs.

These are but a few of the complete Fisher Line. We have pressure regulators of various types and sizes to handle most any requirement.

"POWER PLANT SPECIALTIES" is a book full of interesting information about the Fisher Line. Write for it to-day.

The Fisher Governor Company

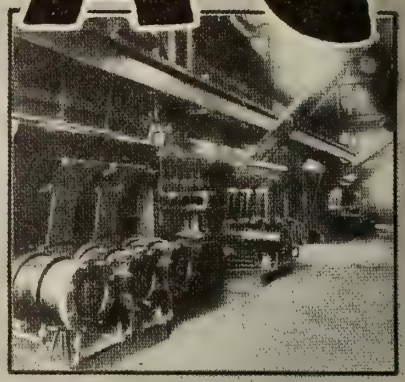
Jones "A-C"



High-Duty Stokers

—*duplicating "test runs" in daily service*

THE high efficiency of Jones "A-C" Stokers is not based on complications that could easily fail when most needed — nor on fine adjustments that would continually require expert attention. That is why their high efficiency and heavy overload capacity is just as apparent in yearly operation as in daily "test runs" conducted under expert guidance.

Jones "A-C" operating records prove that a stoker need not be complicated to fulfill the strictest requirements of high-duty service.

The simplicity of the Jones "A-C" coupled with correct design insures high efficiency, lowers first cost as well as installation cost, insures continuous operation, lowers upkeep and labor costs and reduces the number of repair parts necessary to be kept in stock.

The new "A-C" catalog illustrates and describes the simple design and rugged construction of the Jones "A-C." Ask for a copy of this thorough catalog.

Made in Canada

All Jones Stokers are made in Canada by Canadians and sold for Canadian money at par.

DART UNIONS

Never Loosen Up and Leak

"Dart" Efficiency—

Expansion, contraction or vibration have no effect on these Unions, because "Dart" parts are made of heavy malleable iron and bronze and are sufficiently strong to withstand extremely heavy service, no matter how severe.

Sold by your Jobber.

Manufactured by Dart Union Co., Limited, Toronto

You need the National Stoker

Get away from inefficient hand stoking—without going in for costly mechanical stokers—come in between with the National Hand Fired Stoker which any "green" furnace man can be quickly taught to understand. Pusher rods at front of furnace operate successive banks of Pusher Grates, keeping the fuel moving downward—finally to the Dump Grates. Ensures proper progressive combustion. Any type of fuel can be used. No smoke. No fuel in combustion chamber. No ashes in flues. Increased boiler capacity. Can be installed under your present Boilers. Made here in St. Catharines and sold at a very moderate price.

Detroit V-Type Stokers for dependable, efficient, and economical boiler operation in Public Buildings.

It is a principle of management of public buildings that the corridors, rooms and assembly halls must be adequately heated at all times, and that water, light and elevator service be continuously available.

To secure this dependability special attention must be paid to boiler operation. Recognition of this fact by Engineers and Architects has led to the installation of Detroit V-Type Stokers in hundreds of public buildings.

Typical buildings equipped include:

Methodist Book and Publishing Co., Toronto, Ont
Toronto Housing Co. Toronto, On.
Mount Alto Sanitarium, Mount Alto, Pennsylvania
Municipal Hospital, Pittsburgh, Pennsylvania
Pennsylvania State Hospital, Warren, Pennsylvania
Ohio Valley General Hospital, Wheeling, West Virginia
Secor Hotel, Toledo, Ohio
U. S. Naval Hospital, Reservation, Brooklyn, New York
Broadway Armory, Chicago, Illinois
Central Y. M. C. A., Cleveland, Ohio
Detroit Public Library, Detroit, Michigan
Eastman School of Music, Rochester, New York
Masonic Homes, Elizabethtown, Pennsylvania
Masonic Temple, Pittsburgh, Pennsylvania
Michigan Agricultural College, East Lansing, Michigan
Monroe County Court House, Rochester, New York
Monroe County Penitentiary, Rochester, New York
St. Louis Central Library, St. Louis, Missouri
Wisconsin State Prison, Waupun, Wisconsin
Tuskegee Institute, Tuskegee, Alabama

Detroit V-Type Stokers are a profitable investment because with them: [a] average overall boiler efficiencies of 70-75 percent may be maintained, [b] one man can handle up to 1200 H. P. of boilers, [c] cheaper grades of fuel can be burned than with hand firing.

On every score your boilers should be equipped with Detroit Stokers. Remember, there is a type for every purpose—V-Type Overfeed for natural draft—Single Retort Underfeed for forced draft with boilers developing up to 300-400 H. P.—Multiple Retort Underfeed for large boilers.

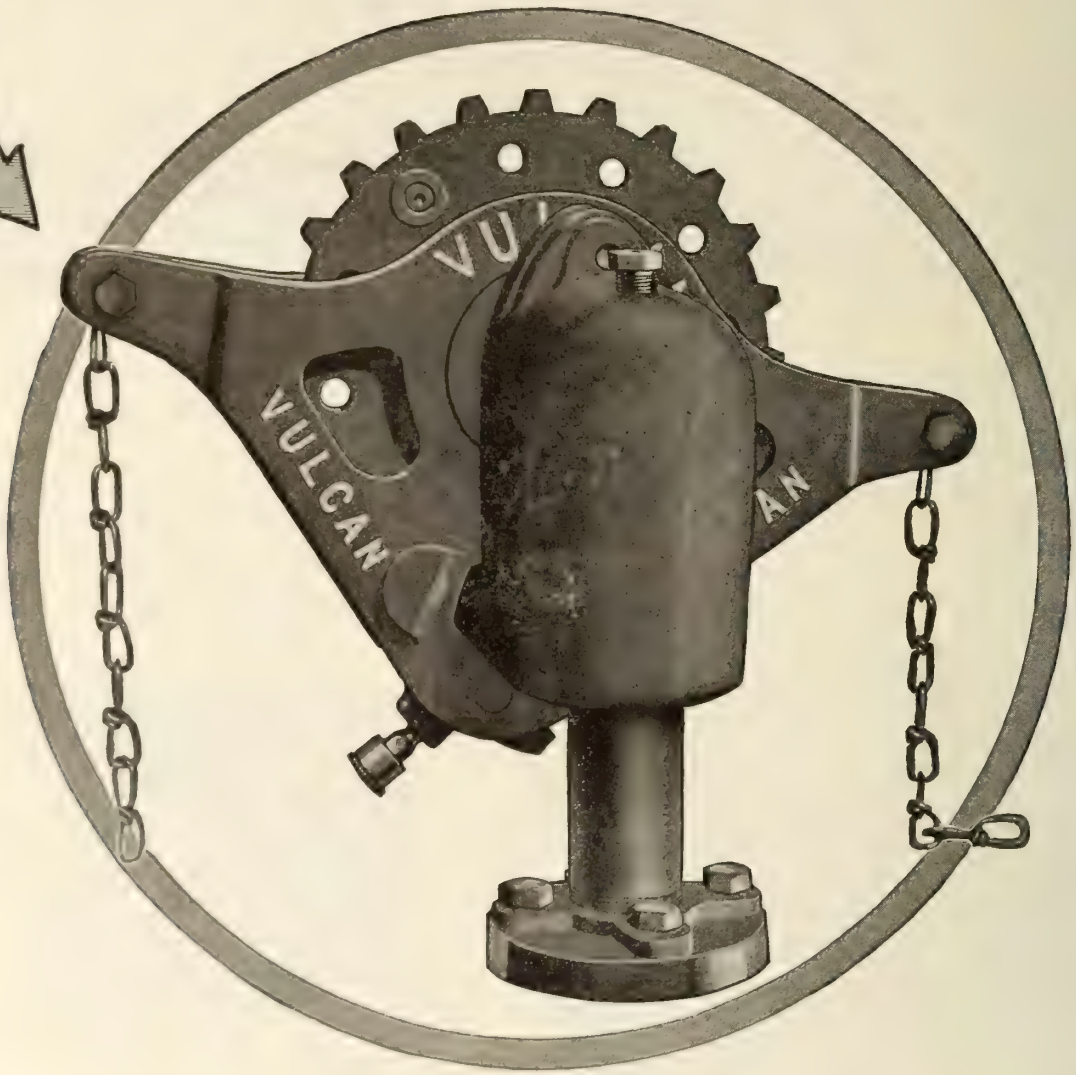
Introducing the



The Vulcan Ratchet Operating Head

Insuring "step-by-step" rotation of soot cleaner element
and more THOROUGH soot removal than ever

Newest and Most Advanced Principle in Soot Cleaner Operation

The Vulcan Soot Cleaner Company is pleased to announce what it is convinced is the most advanced principle in soot cleaner design and operation so far offered to the power plant engineers of America.

This new principle is embodied in the new VULCAN RATCHET OPERATING HEAD, illustrated on the opposite page.

For many years a small percentage of operators of soot cleaners have complained that their cleaners did not thoroughly remove the soot accumulations. In a majority of cases, investigation disclosed the fact that the cleaning elements either were being operated too fast, or rotated by careless workmen through only a portion of the entire sweep, thus preventing the cleaner from doing its proper work, through failure to give the steam jets time enough thoroughly to clean the tube surfaces.

The new VULCAN RATCHET OPERATING HEAD is designed to take the mechanical operation of the cleaning element entirely out of the hands of the operator! The new Head is so constructed that when the operator pulls the chain the element is rotated only a short distance, and can be turned no farther until the ratchet frame has been returned to its original position. Then, and only then, a pull on the chain causes the element to rotate another space. Between the lulls in operating the new Head, the steam jets have an opportunity to concentrate upon a definite section of the tube surface for a length of time sufficient to insure a thorough removal of the soot. When the complete arc of rotation has been attained in one direction (which is limited by special "stops" especially set for the purpose), the mechanism' AUTOMATICALLY reverses itself and the cleaning element moves back in the same manner through the same arc. Any soot that may have re-deposited after the first rotation is completely removed on the backward travel.

Since the first requirement of every soot cleaner is to remove the soot, it will be obvious that this purpose is accomplished by the new VULCAN RATCHET OPERATING HEAD, no matter who operates the cleaner or how careless and inefficient a workman may be.

Special Features of the New Vulcan Head

There are five principal features to the new VULCAN RATCHET HEAD, which are worthy of consideration. These are:

(1) It absolutely prevents the man operating it from neglecting any part of the complete sweep of the cleaning element;

(2) It substitutes a uniform rate of speed of rotation, in a step-by-step movement, controlled almost entirely by the Head itself, in place of the old, irregular, uncertain rate controlled by the whim of the operator and his desire to get through with the job;

(3) It assures a considerable saving in quantity of steam used, because the operator knows that he has to make the sweep only once in each direction, and can stop when that has been accomplished;

(4) It provides the operator with a clearly defined task, instead of a vague and indefinite one;

(5) Above all, it entirely eliminates wrong methods of soot cleaning, and is an assurance of more satisfactory cleaning results.

The new Head is remarkably simple and strong. Its action is positive and sure. There is not a part to slip out of place, and thereby throw the whole device out of action. The chain is securely riveted to the ends of the ratchet frame and no amount of pulling or jerking will tear it loose.

This new Head is operated INDEPENDENTLY OF THE VALVE. Therefore, should either accidentally fail, the whole Cleaner System is NOT put out of commission while repairs are being made. The value of a soot cleaner depends upon its usefulness. If the temporary failure of one cleaning element means that the whole system is out of use until that one element has been repaired, clearly the real value of the Cleaner is seriously impaired.

A special Bulletin, thoroughly illustrating and describing the new VULCAN RATCHET OPERATING HEAD is now in course of preparation. If interested in this newest principle in soot cleaner operation, ask to be put on the list to receive BULLETIN No. 549 when it is ready for distribution. ***Meanwhile, upon request, our nearest representative will gladly call and demonstrate the new head at your office.***

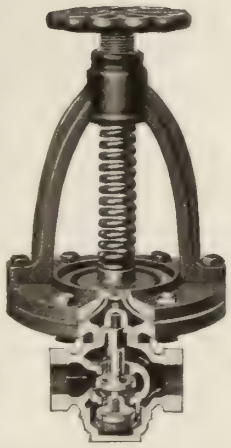
CURTIS ENGINEERING SPECIALTIES

Comprise a line of devices that have stood the test of years for the utmost in efficiency. They are built for dependable and enduring service. Scrupulous care in the selection of material and in construction, with adherence to the highest engineering standards, have won them a commanding position. The



CURTIS WATER-PRESSURE REGULATOR

will deliver water into service pipes at any desired pressure, regardless of any fluctuations of outside pressure.

Trouble with rust or clogging with sediment is prevented. Waste of water in domestic use by flying or spattering is avoided by the reduced pressure. This also prevents water hammer or concussion and prevents wear and tear on all packings and seats in valves and faucets, thus eliminating frequent plumbing bills. Adapted for use in pulp and paper mills, hotels, public buildings and dwelling houses. For ¾ in. to 2½ in. pipe, screwed. For 3 in. to 8 in. pipe flanged.

The Curtis Line of Steam Specialties contains many other notable devices. They are fully described in our No. 50 catalogue. Write for a copy.

The CAMBRIDGE PORTABLE CO_2 and Temperature Indicator

Weight — 14 lbs.
Size — 13 x 7 x 5½ ins.

Demonstration on Request

WITH this instrument, both the temperature and percentage of CO_2 in the flue gases can be indicated on the one instrument, the time lag being practically negligible.

The instrument is very portable and is complete in itself. In operation it is exceedingly simple, no chemicals being required; the results are reliable and it is always ready for immediate use. There is nothing to get out of order. It is particularly suitable for Consulting and Inspecting Engineers, also for large power plants as a test instrument to check permanent installations.

LEONARD

Your Belting Should Be "Oak Tanned"

YEARS ago, the process of Oak Tanning was a jealously guarded secret in England. To-day, it is general knowledge among experts in all parts of the world, although Oak Tanning is acknowledged, without question, as superior to any other process, it is a slow —very slow—process and is not used generally on account of the expense entailed.

Since D. K. McLaren Belting has been made, however, every inch has been subjected to this Long-Time Genuine British Oak Tanning. It is this process, indeed, that not only adds to the original toughness of the hide, but imparts that wonderful flexibility and stretchless quality that has established for D. K. McLaren's Belting a world-wide reputation for Dependability.

In addition to this, however, it should be borne in mind that only the back—the toughest part—of hides selected by experts is used in manufacture.

The Oak Leaf is your guarantee that you are getting Genuine British Oak Tanned Belting. Users of experience know that it is worth while to make sure the Oak Leaf is on every length of Belting they buy. They know that it means real "service on the pulley" and the utmost efficiency even under adverse conditions. The Oak Leaf tells them that every inch has been put to the severest tests before leaving our factory.

Truly, D. K. McLaren's Belting is the royal road from the source of power to the pulley, for it delivers power with the least loss and gives a minimum of trouble doing it.

RAYBESTOS TWIST
RAYBESTOS DISCS
REDBLAC SHEET PACKING

THE CANADIAN RAYBESTOS COMPANY,

Style 550

Pack all Valve Stems with

Raybestos TWIST

and you will not have to pack them so often

Made from long-fibre silky asbestos and thoroughly lubricated with high grade mineral oils and graphites. Will not harden or dry out.

Recommended for use in any plant—engine room—machine shop—garage—ship—dry-dock—laundry—plumbing shops—steam fitters. It will pack all styles of globe angle and stop valves—small piston rods—small pump rods—radiators. Used for water, steam, air, etc.

This twist is made from individual treated strands of asbestos twisted into ⅛ inch roves, then retwisted, using ⅛ inch roves, into larger sizes of finished packing.

Engineers can take large size, we will say ½ inch, and use for stem requiring ½ inch packing, or can untwist and take smaller strands for ¼ inch or 3-16 inch needs.

Doyton-Dowd Centrifugal Fire Pump

Arranged with dual drive consisting of electric motor and auxiliary gasoline engine. Capacity 500 gallons against a head of 100 lbs., speed 1450 R.P.M.

DAYTON-DOWD Fire Pumps

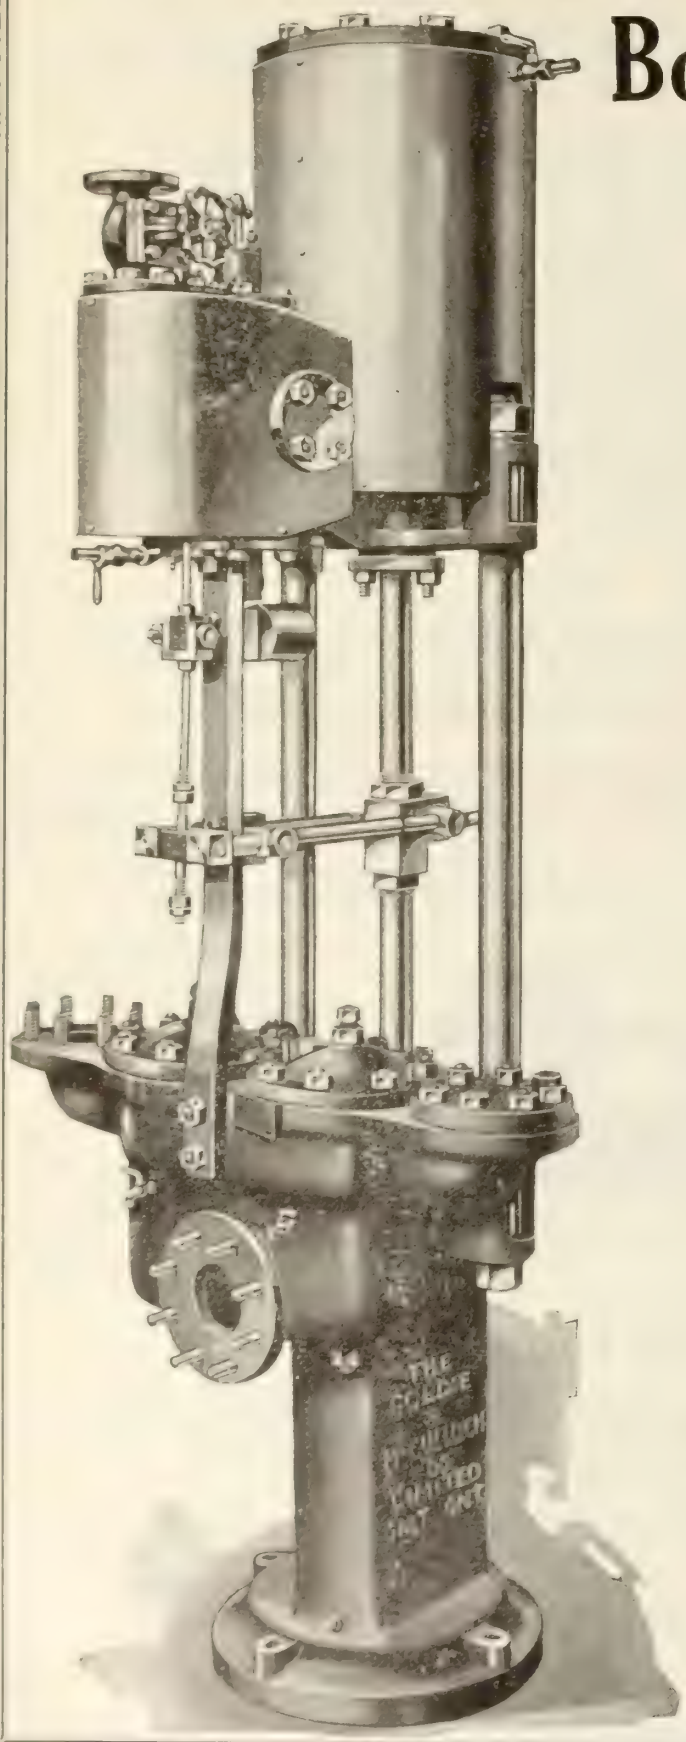
This Double Drive Fire Pump is a convenient method of installation and affords perfect dependability in case of failure of the electric or steam power. It consists of an electric motor or turbine and a gasoline engine, one mounted on each side of the fire pump and constitutes a most reliable standby to meet any emergency.

The installation is approved by the Canadian Board of Fire Underwriters. Write for bulletins of Dayton-Dowd Pumps for every service.

THE ARTHUR S. LEITCH COMPANY Limited

1001-2 Kent Bldg. **Toronto, Ontario**

Vertical Simplex Double Acting Boiler Feed Pumps



Reliable, Economical and Highly Efficient

THESE Pumps are designed and built to meet the requirements of the modern power plant.

Their slow steady speed gives a very high efficiency. Actual tests showing 95% in the water end as against 70% in a horizontal pump, with both pumps working under similar conditions.

In the Vertical Simplex Pumps the pilot or timing valve also acts as a cut-off valve, allowing steam to be used expansively and making possible the slowing down of movement at end of stroke.

You incur no obligation by consulting with our Engineering Department. We shall be glad to supply more detailed information on request.

Bilge and Ballast or Low Duty Pumps

These pumps are of the same general design as the Vertical Boiler Feed Pumps, but are primarily intended for discharging much larger volumes of water against low heads or pressures.

Kitchener Is the Convention City

The Thirty-Third Annual Convention of the Canadian Association of Stationary Engineers Will be Held on June 27-28-29—An Interesting Programme Has Been Arranged, Both for Business and Pleasure.

IT SCARCELY seems a year since exhibitors and delegates were congratulating each other on the wonderfully successful convention just concluded at Ottawa. Well, it is perhaps just a little short of a year, but only a matter of a week. On June 27th, 28th and 29th the C. A. S. E. will hold the annual convention at Kitchener, and the prospects are for a bumper gathering of delegates and exhibitors, not forgetting the visitors.

Old time members of the Canadian Association of Stationary Engineers, have pleasant recollections of conventions held in other days, when the town was called Berlin. Some of these old boys will close one eye and look very mysterious and wise when these times are recalled, and they can tell stories, if so minded, of some nights when revelry stole abroad.

Well, it is hard to tell what may happen at a convention, and perhaps some of them will find a way to raise the spirits of departed days. In these days of spiritualism anything is possible. Did not even some of our staid and respectable M.P.P.'s manage to stage a party without getting into trouble? Surely an engineer is as clever as an M.P.P. If he were not, there would be a number of manufacturing plants going out of business before long.

A Fitting Spot

The town of Kitchener is without doubt as good a town as could be found to hold a convention of power plant engineers, and an exhibition of power plant apparatus. It is a manufacturing town in a large way. The first thing one sees on entering and the last on leaving is a manufacturing plant of some kind. There are three principal lines of endeavor, namely, furniture, shoes, and rubber products, and some of the rubber factories are well worth a visit. Not only are they worth looking over, but they invite one to do so, the only formality required being the issuing of a pass in the office.

Kitchener, besides being a manufacturing town, is a town of homes. Nearly everybody in the place owns his own home, and the majority of them are set in spacious grounds. In this respect they contrast very favorably with some more pretentious homes in other cities, which seem to be pining for breathing space. A story is told of a visitor to Kitchener, who, after being driven all over the town, up one residential street after another, finally arrived back at his hotel. His guide asked him how he liked the city, and the reply was "Fine, but where do the working people live?" When he discovered that he had been viewing where the working people lived he was a much astonished visitor.

The Dominion Tire Plant

One of the largest plants in the city is that of the Dominion Tire, just a little distance out of the general manufacturing district, but within easy access either by walking or street car from the main street. It is a handsome building, and stands in beautifully-kept grounds. The power plant will be found interesting from the point of view of the visiting engineers, and those wishing to see through it can arrange to do so, by request.

The power plant is primarily used to supply steam for process work, although there are also a number of steam auxiliaries such as air compressors and hydraulic pressure pumps, with of course, the usual feed pump arrangements. In case of emergency there is also installed a 750 k. w. turbo generator and this has been called into service on several occasions during the past winter.

The boiler plant consists of B. & W. boilers double drum 250 h.p. each, and two Goldie & McCulloch water tube boilers of 330 h. p. each, making a total of 1,660 boiler horse power. They are all fitted with Jones' underfeed stokers, while there is a complete set of Republic Co. recorders and indicators, the indicators being mounted on the boiler fronts where the firemen can see them at any moment. There is a water softening plant of sufficient capacity to supply all the boilers, and this has had a very beneficial effect since its installation in eliminating shut downs for cleaning purposes, as well as increasing the efficiency of the plant by reason of preserving clean heating surfaces.

The engine room contains the air com-

VIEW OF POWER PLANT DOMINION TIRE SYSTEMS
Building to left of stack is boiler room, and to the right is the water softening plant and compressor and pump rooms.

pressors for supplying air to the factory for process work, and the hydraulic pumps for the presses, etc., are also located in this room. There is an interesting battery of recording instruments, in connection with the boiler room. An interesting little kink was observed in connection with a small air compressor which has to supply air at 200 lbs. pressure. This is a two-stage machine, and when first put in was ample for the work it had to do. As is usually the way in a plant of this kind, the factory gradually kept adding to the load until the compressor could not supply sufficient air at the requisite pressure.

This difficulty was overcome by introducing the discharge from another compressor working at 75 lbs. per sq. in. to the low pressure side of the two-stage machine thus enabling it to perform the necessary work without any trouble.

In front of the building is a large spray pond, installed at the time the turbo generator was installed, for the purpose of cooling the circulating water for the condenser. This is used for cooling water in connection with process work in the factory, but apart from that, it has a delightfully cooling appearance on these hot summer days. On the lawn in front of the building there are a number of tennis courts laid out, for the benefit of the employees.

The illustrations herewith show the extent of the power plant in some degree, but of course, this is but a mere sketch of what there is to be seen.

The Ames Holden Tire Co. also have a large factory right at the corner of King Street, outside of which is a large sign inviting visitors to look over the plant, and also offering the use of the grounds to park their automobiles in the meantime.

The Twin City

The sister city of Waterloo is connected to Kitchener by street car, and is distant about three miles, in a straight line along King Street. This intervening distance is practically all built up, many beautiful homes being situated along the road. The main office of the Mutual Life Insurance Co. is situated on this road, and is a very beautiful building, standing in spacious grounds. Waterloo itself contains a number of factories, besides the famous Kuntz Brewery, which of course has now but little interest for residents of Ontario. However, it is probable that some of the delegates might like to look over it, and observe the interesting processes, of what may some day be a lost art.

The Meeting Places

The exhibition of power plant machinery will be held at the hall of the Dominion Tire Systems, 119 King [illegible], while the Grand Lodge meetings [illegible] be conducted at Moose Hall, on Foundry Street, a couple of minutes' walk from the exhibition hall. As usual there will be a good number of firms exhibiting their specialities, while the entertaining of the guests and delegates is in the capable hands of the Exhibitors' Entertainment Committee. The following firms have reserved space for exhibits:

Exhibitors

Jas. Morrison Brass Manufacturing Co., Toronto; Babcock & Wilcox, Montreal; Black Donald Graphite Co., Calabogie; Darling Bros., Montreal; Stephens Chemical Co., Toronto; C. B. Turner & Co., Toronto; Empire Brass Manufacturing Co., London; Dart Union Co., Toronto; Power, New York; W. R. Sexton Boiler Setting Co., Toronto; G. E. Cole, Toronto; Canadian Manufacturer, Toronto; A. H. Winter Joyner, Ltd., Toronto; E. Leonard & Son, London; Thompson Gordon, Ltd., Hamilton; H. Mueller Manufacturing Co., Sarnia; Quaker City Rubber Co., Philadelphia; Power House, Toronto; Crane, Ltd., Montreal; Waterous Engine Works, Brantford; Lunkenheimer Co., Cincinnati; Garlock Packing Co., Hamilton, Dearborn Chemical Co., Toronto; Jenkins Bros., Ltd., Montreal; Goldie & McCulloch Co., Galt.

The Exhibitors' Association Officers

The officers of the Exhibitor's Association are as follows:

Officers of Kitchener Lodge

Fred Pflug, president; Chas. Murril, vice-president; Conrad Ott, recording secretary; Charles Emery, financial secretary; Leander Lindsay, conductor; Ed. Klein, doorkeeper.

The Official Programme

Monday, June 26

Emergency meeting of the Grand Lodge officers at 8 p. m.

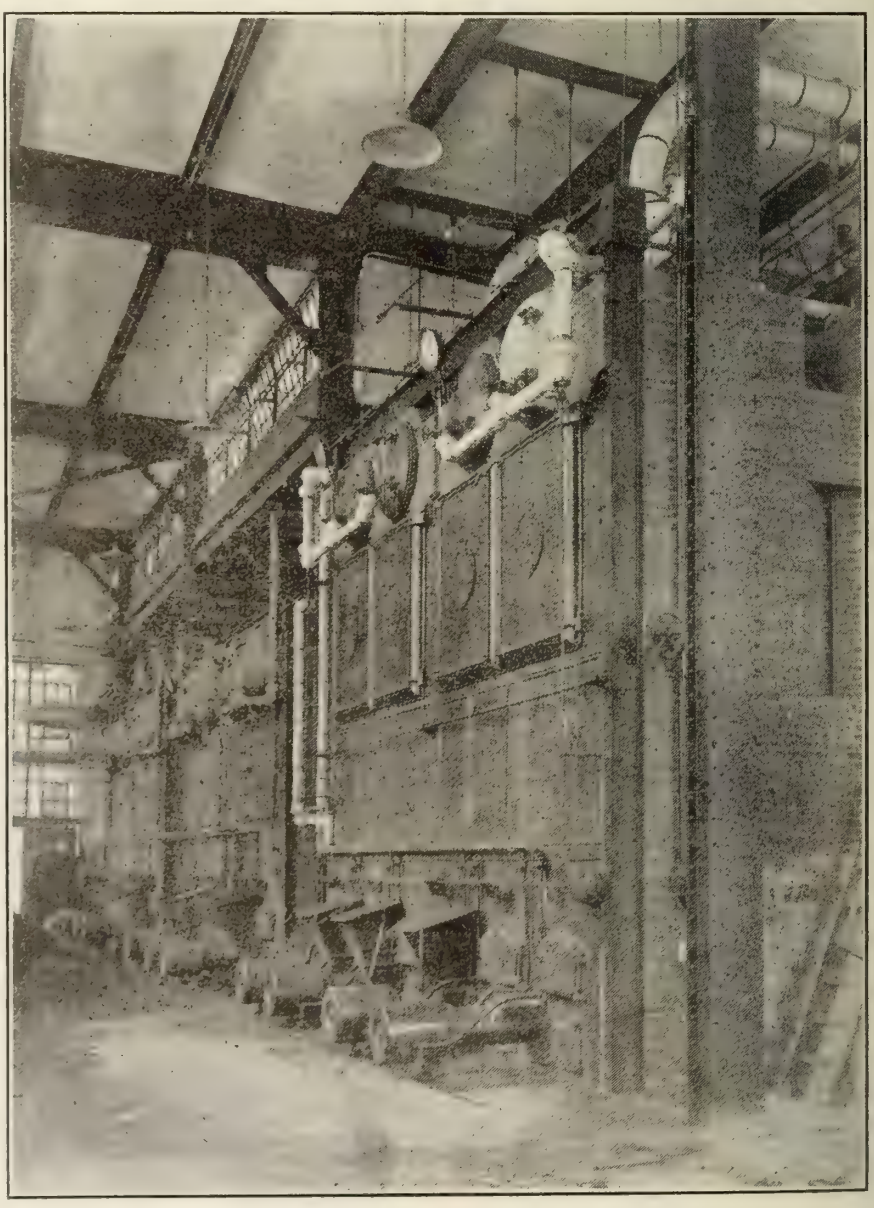
Tuesday, June 27

Opening session Grand Lodge at 9 a. m.

Three minutes' silent respect for the late A. M. Wickens, past president.

Receiving president's and secretary's reports.

Adjourn 9.45.



BOILER ROOM OF DOMINION TIRE SYSTEMS

Four double drum 250 H.P., B. & W. boilers and two double drum Goldie & McCulloch 330 H.P. each.

Official welcome by the Mayor of Kitchener at 10.00.

Official visit to Exhibition Hall by the members of the Grand Lodge.

Grand Lodge session 1.45 p. m.

Grand Lodge session at 8.00 p. m. to consider constitution and by-laws.

Meeting local lodge to which all visitors are invited. Mr. Mess will give an illustrated lecture on flow meters.

Ladies will be entertained by the local lodge.

Wednesday, June 28

Grand Lodge meets at 9.00 a. m.

Sports 2.00 p. m. Races and games, for which valuable prizes will be given.

Entertainment in Exhibition Hall at 8.00 p. m. There will be a musical programme, drawing for prizes and presentations by winners of the Grand Lodge Educational Contest and Membership contest. These prizes have been donated as follows:

Educational: First, Dominion Flow Meter Co.; Second, Moore & Goldie, Montreal; and Third, J. J. Sullivan, president, No. 6, Ottawa.

Membership: First, Fred Harper, Kingston, president, Grand Lodge; Second and Third by L. J. Ellis, secretary of the C. A. S. E.

Thursday, June 29

Grand Lodge meets at 9.00 a. m. for the election of officers and the selection of place for next convention.

Annual meeting Exhibitors' Association will be held at 10.00.

Installation of Grand Lodge officers at 2.00.

A special meeting of the newly elected officers of the Grand Lodge for the appointment of committees.

God Save The King

Wednesday Night

Chairman ..... E. F. Hetherington.
Recitation .... Dorothy Ott
President's Ochestra .....Pres. Pflug's Quartette.
Marimbaphone Duet .....Ott Bros.
Piano Solo .... Anita Stauffer
Solo .... Bob Jones
A Laugh With Jack Armour.
Solo .... E. F. Hetherington

Drawing—10 p. m. Wed. Evening

Engineers:—
1—Fountain pen.
3—Pipe
9—Ratchet screw driver.
15—Hat brush.
21—Mystery box.
Ladies:—
4—Silver fruit ladle.
8—Silver sugar shell.
12—French ivory hand mirror.
16—Mystery box.

Sports

1. One hundred yard dash—Engineers and Exhibitors.
2. Balloon race—Engineers' wives only.
3. One foot hop race—Engineers and Exhibitors.
4. Candle race.
5. Backward running race—Engineers.
6. Ladies' clothes-pin race.
7. Men's smoking race—Engineers only.
8. Potato race—Engineers' wives only.
9. Wheelbarrow race.
10. Little boy's race.
11. Little girls' race.
12. Soft ball game—Engineers and Exhibitors.

Honorary presidents—F. A. Pflug, Kitchener, and Conrad Ott, Kitchener.

Past president—C. B. Turner, 894 Bathurst street, Toronto.

President—Grant E. Cole, G. W. Cole Limited, 2002 Dundas West, Toronto.

First vice-president—J. Thompson, Dearborn Chemical Co., 2454 Dundas West, Toronto.

Second vice-president—R. H. Lyons, Garlock Packing Co., Ltd., London.

Secretary—Gordon C. Keith, The Canadian Manufacturer, 51 Wellington St. West, Toronto.

Assistant Secretary — Bob Jones, France Packing Co., Tacony, Pa.

Treasurer—Lloyd M. Archibald, Dart Union Co., Ltd., 93 Niagara St., Toronto.

Exhibition Committee—Evan A. Peterson (chairman), Crane Ltd., Montreal.

Entertainment—E. F. Hetherington (chairman), Goldie & McCulloch Co. Ltd., Galt.

Reception — Arthur Betton, James Morrison Brass Mfg. Co. Ltd., Toronto.

Next exhibition will be held at Kitchener, June 27, 28 and 29, 1922.

OFFICERS OF EXHIBITORS ASSOCIATION

The annual exhibition of power plant equipment and supplies will be held in Kitchener, June 27, 28 and 29, 1922.

Performance of a 60,000 Kilo Watt Station

The Colfax Station, Duquesne Light Co., Cheswick, Pa., Has Been an Interesting Example of Steam Central Power Plant Practice Since its Erection—This Article Deals With Operation Features

By C. W. E. CLARKE

Read before the American Society of Mechanical Engineers.

IT IS the purpose of this paper to describe in some detail the operation of the boiler plant in the Colfax Station of the Duquesne Light Co., located at Cheswick, Pa. Fig. 1 is a cross-section of the boiler house and part of the turbine room of this plant. The Colfax Station at present contains one three-element-compound Westinghouse turbine of 60,000 kw. capacity and an additional similar machine will be installed this summer. The present plans for this station contemplate an ultimate capacity of 360,000 kw. The boiler plant contains seven boilers, 18 tubes high by 51 wide, each containing 20,867 sq. ft. of heating surface; and four additional boilers 20 tubes high by 51 wide, each containing 22,914 sq. ft. of heating surface, are being installed this summer. The station is designed for base-load operation. Under present conditions it is possible to maintain a load in excess of 50,000 kw. for most of the day. For the night periods, from about midnight until seven or eight in the morning, the load may fall as low as 30,000 kw.

The boiler room was designed with a view to securing the highest ultimate efficiency in point of fuel, labor and fixed charges. It will be noted that the labor per horsepower is very small. The area covered by the boiler house per boiler horsepower is only 1.37 sq. ft.

Fuel and Fuel Handling

Coal is brought to the station on a standard-gauge railway in 50-ton hopper-bottom cars from the Harwick Mine, owned by the Duquesne Light Company and located about a mile and a half from the power station. A space about 1,000 by 400ft. just north of the power station is provided for coal storage and is large enough for the storing of about 150,000 tons of coal. A rope-operated gantry bridge is now being erected for handling coal into and out of this storage.

At the plant, coal is dumped into receiving hoppers under the tracks. Crushers are located below the hoppers and the crushed coal is raised by two pivoted bucket elevators to distributing belt conveyors over the bunkers. As the coal goes to the crushers, water is added to help keep down the dust, and as an aid to combustion.

A representative sample of each day's coal is secured by taking individual samples of about 75 lb. from each carload as the cars are dumped. These are placed in airtight cans and so kept until they are to be used. The whole day's samples are then run through an automatic crushing and sampling machine which extracts a 3 to 4 per cent. sample, amounting at the present time to about 40 lb. This 40-lb. sample is quartered on a clean floor and two 3-lb. samples are taken out and put in sealed containers. One of these is sent to the laboratory for analysis and the other is held at the plant until satisfactory analysis of the laboratory sample has been completed.

To secure samples of the coal as fired, a sample of about 1,000 lbs. is also taken from the stoker hoppers at 7 a. m. daily. This sample is treated in the manner described above. Table 1 shows the average of a number of approximate analyses of the fuel and Table 2 a representative ultimate analysis.

The coal bunker is of reinforced concrete and has a capacity of about 240 tons per boiler. Coal is not permitted to remain in the bunker longer than about three days, which practically eliminates any possibility of spontaneous combustion in the bunkers. Distribution of the fuel to the individual stoker hoppers is by means of two weighing lorries each having a capacity of 10 tons. A number of openings in the bottom of the bunker are provided with short cast-iron spouts equipped wiith chain-operated gates and

TABLE I. PROXIMATE COAL ANALYSES

	As Received		Moisture-Free	
	As Unloaded	As Fired	As Unloaded	As Fired
No. of samples	25	30	25	30
Moisture, per cent.	2.9	4.1	..	..
Volatile matter, per cent.	34.5	34.1	35.5	35.6
Fixed carbon, per cent.	53.0	52.5	54.6	54.5
Ash, per cent.	9.6	9.3	9.9	9.6
Total, per cent.	100.0	100.0	100.0	100.0
Sulphur, per cent.	1.0	1.1	1.1	1.2
Calorific value, B.t.u. per lb.	13,351	13,237	13,758	13,895

The difference in moisture between the coal as unloaded and as fired is due to the addition of water at the crushers mentioned above.

TABLE 2 REPRESENTATIVE ULTIMATE ANALYSIS OF FUEL

	As Received	Dry Coal	Moisture-and Ash-Free
Ash, per cent	8.88	9.30	....
Sulphur, per cent	1.09	1.14	1.26
Carbon, per cent.	72.92	76.40	84.23
Hydrogen, per cent	5.39	5.12	5.64
Nitrogen, per cent	1.49	1.56	1.72
Oxygen, per cent	10.23	6.48	7.15
Total, per cent	100.00	100.00	100.00
B.t.u. per lb. by calorimeter	13,202	13,832	15,251
B.t.u. per lb. by analysis	13 199	13,828	15,246.

permit coal to be taken from any part of the bunker.

Stokers and Clinker Grinders

Each stoker is provided with an extension hopper, the capacity of the grate and hopper together being about 25,000 lbs. The stokers are of the Westinghouse underfeed type and have 17 retorts of 20 tuyeres each. The projected grate area of each stoker is approximately 403 sq. ft.

Each stoker is driven by a 15 h. p. variable-speed direct-current motor, equipped with both armature and field control. Current for these motors and for the clinker-grinder motors is supplied by two 2,200 kw. 440 volt a.c. to 125 volt d. c. motor-generator sets located in the auxiliary bay of the turbine room.

The stoker operator is guided entirely by observation of the fires and of the wind-box pressure. The forced-draft-fan speed and consequent wind-box pressure are automatically controlled by variations of the steam pressure in the main header. Wind-box pressure is for this reason somewhat of an indication of load condition. The pressure over the fire is maintained at from 0 to minus 0.1 in. of water by means of balanced-draft damper controllers.

In this type of stoker the upper and lower rams are linked together, but the movement of the lower rams is made much less than that of the upper through lost motion in the linkage. In case the fire piles up on the lower end of the grate this lost motion may be taken out by means of U-links which are left on until the fire is in proper condition. The stoker drive is capable of very close speed regulation and with ordinary care and the occasional use of the U-links, an even fuel bed suitable to the load may be maintained.

Each boiler is provided with an individual instrument and control board shown at the right in Fig. 2. At the top are two pressure gauges connected to either end of the boiler drum. Between them is a three-in-one draft gauge which indicates the pressure in the wind box, over the fire, and in the boiler uptake. Below the draft gauge is a combined CO_2 and furnace-pressure recorder. Each of the two boiler-feed lines is provided with a Simplex venturi meter, the recorders for which are at the bottom of the two side panels. Each of these meters has a capacity sufficient to feed the boiler at over 250 per cent. of rating. The stoker and clinker-grinder motor controllers are bolted to the frame below the board, with the stoker-motor controller in the centre and the clinker-grinder controllers at either side. This places practically the entire control for each boiler at one point so that but one stoker operator is required for 4,175 nominal boiler horsepower, which is over 9,000 developed boiler horsepower at 220 per cent. rating, the normal daytime condition. No centralized control is provided as such a system is of doubtful advantage. The management of stokers, aside from that which can be made automatic, must be almost entirely through visual observation of the fuel bed. There are few factors of stoker control that can be centralized in such a way as to either save labor or fuel. Fig. 2 shows the general arrangement of the boiler, gauge board, etc.

When this installation was first put in operation some difficulty was encountered with clinkering. After considerable experimenting it was definitely determined that this was due in part to periods when there was pressure over the fires and in part to improper water distribution in the clinker pits. Particular care is now taken to maintan a furnace pressure below atmosphere at all times, and the water distribution has been improved as described below with the result that clinker trouble has been practically eliminated.

Some trouble was at first experienced

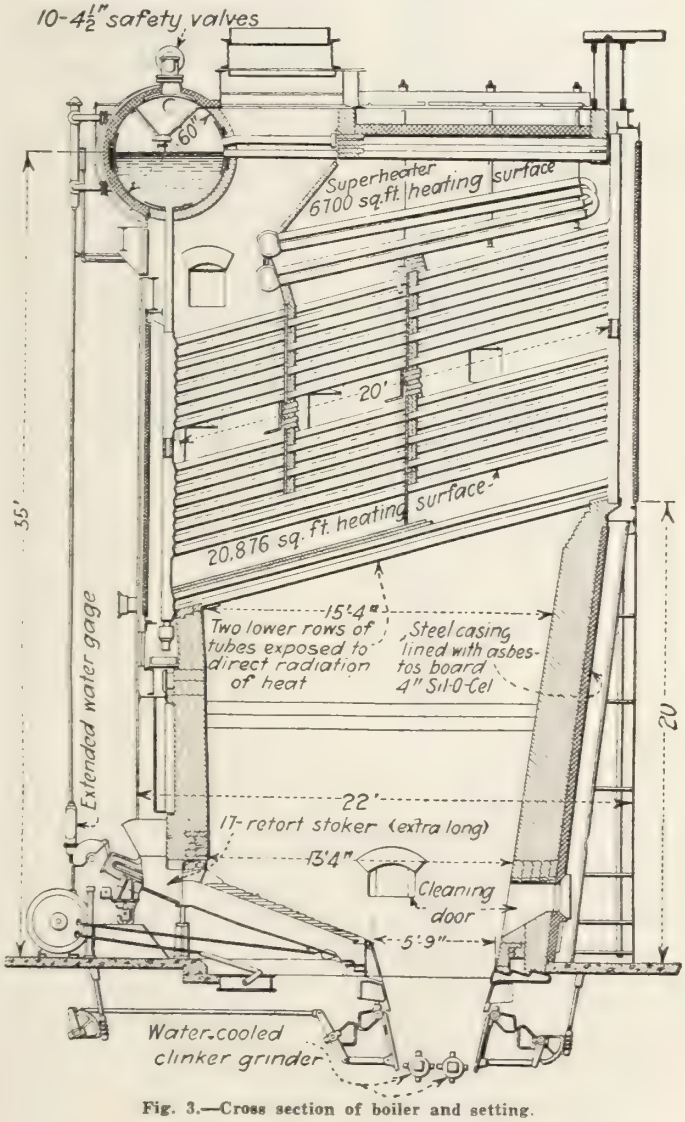

Fig. 3.—Cross section of boiler and setting.

due to burning out of the lower front-feed wedges. This trouble has been largely eliminated by allowing air to blow through from the wind box, thus keeping the wedges cool. To facilitate replacement, the air-box tops and grinder-pit aprons have been made sectional instead of as in the original design.

The stokers are provided with double-roll clinker grinders, divided in the centre, with the rolls turning toward each other. The two halves are driven by separate motors, separately regulated, giving individual control over the two halves of the grinder. The rolls are driven through reciprocating pawls and ratchets which may be disengaged on either roll. It has not been found desirable to operate the rolls continuously. Under normal operating conditions the rear rolls are operated rarely, the front rolls being run for periods of from two to five minutes in every twenty minutes, which means from six to eight revolutions in one hour. Grinder operation is governed entirely by observation of the ash pit. The top of the ash bed is kept above the top of the rear wall air boxes.

To prevent the formation of clinker masses in the ash pit and to cool the clinker rolls, water is introduced above the rolls. Upper-grate box tops having a down-turned projecting lip are installed, under which lip is placed a horizontal spray pipe perforated with quarter-inch holes six inches apart. This pipe introduces the water high up in the ashpit and quite effectually prevents the formation of hard clinker masses. The introduction of water high up in the ashpit tends to quench the ash before combustion is as complete as could be desired, thus increasing the amount of combustible in the ash. At the present time this seems to the lesser of two evils. The sprinkling system requires about fifty gallons per minute for each boiler.

Ash Handling and Sampling

The clinker grinders discharge into firebrick-lined reinforced concrete ash hoppers with an approximate capacity of 60 cu. yd. These hoppers will hold the refuse of from one and a half to two days' normal operation. It is the regular practice, however, to remove the refuse from all working boilers twice a day.

A sample of ash from each boiler is taken every other day. A gross quantity of about 400 lb. is taken from the total 24-hr. dump from each boiler, the sample being taken from six different points in the pile, at a depth of about three feet below the surface of the pile. The whole sample is then hand-crushed and quartered until about three pounds remain, which is sealed in a container and sent to the laboratory to be analyzed for combustible. The method of analysis is in accordance with the specifications of the American Society for Testing Materials.

Boilers

There are at present seven boilers of the Babcock & Wilcox cross-drum type, 18 tubes high by 51 wide, with 20,876 sq. ft. of heating surface and with the so-called "Alert" baffling. There are 918 tubes in each boiler proper and 102 circulating tubes connecting the uptake headers with the drum, making 1,020 tubes in all. Fig. 3 is a cross-section of the boiler and setting. It will be noted that the combustion space is large. The present settings contain 0.345 cu. ft. of combustion space per square foot of heating surface and those to be installed this summer will be the same.

Each boiler has two water columns with high- and low-water alarm whistles. When one of these alarms sounds the operator examines the feed regulators for possible sticking, and if necessary cuts it out and uses hand control until repairs can be made. If the regulator is found to be all right he checks up the feed pressure and if necessary starts another pump or puts on the auxiliary feed.

Furnace temperatures vary from 2,500 to 2,800 deg. fahr.; at the top of the first pass this approximates 1,000 deg. fahr., between the second and third passes it is 530 deg. fahr., and the exit gas temperature varies from 450 to 480, usually being about 470 deg. fahr. Fig. 4 is a chart showing the temperature range and gas velocities through the boiler. Typical temperature and CO_2 traverses are given in tabular form in the complete paper.

Slagging on the boiler tubes is slight and has never been sufficient to cause trouble. The use of distilled make-up water eliminates trouble from scale and consequent tube renewals. The total commercial operation of the seven boilers now installed has been approximately 39,922 boiler-hours up to February 1, an average of 5,703 hr. per boiler and but two tubes have been replaced.

Each boiler is equipped with eighteen soot-blower elements, nine on each boiler. These soot blowers are operated three times a day with the dampers opened wide.

In the past boilers have been taken off for cleaning and repairs after 30 to 45 days of service, but it is expected that in the future service periods will be from 90 to 100 days. This increase is due to some slight modification of the settings and increased knowledge of the performance of the equipment. The work of inspection and repair ordinarily takes from 10 to 14 days. Full efficiency is not reached until from four to seven days after the boiler is put on the line.

The settings are of firebrick throughout, the walls being 18 in. thick. Sil-O-Cel and asbestos millboard fill the 4¼ in. space between the firebrick and the steel casing. Deterioration of the setting is very slight.

The formation of clinker on the furnace walls is prevented by air cooling, Bernitz and Drake blocks being used. These blocks did not altogether prevent clinkering on the side walls and side-wall tuyeres have been installed, which have practically eliminated it.

The superheaters are located over the tube tanks between the first and second pass. Considerable trouble has been experienced because of insufficient superheat. The normal superheat should be

TABLE 4 OPERATING FORCE FOR THREE EIGHT-HOUR SHIFTS

Title	No. required per shift 1 unit	2 units	Duties
Boiler engineer[1]	1	1	Responsible for the proper operation and maintenance of all boiler-room apparatus and coal and ash-handling systems.
Boiler operator	1	1	In general charge of boiler operation during his shift. Reports to boiler engineer.
Stoker operator	3	6	Each operates two boilers, including stokers, clinker grinders, dampers, etc.
Soot-blower operator	1	1	Operates soot blowers on each boiler once during the shift.
Larry operator	1	1	Weighs and distributes coal to stoker hoppers, keeping all active boilers supplied. In order to provide a consistent record for daily heat balance, hoppers on all active boilers are filled full between 11.30 and midnight.

[1]Day shift only.

TABLE 5 COAL AND ASH-HANDLING FORCE, ONE TEN-HOUR SHIFT ONLY

Title	No. required 1 unit	2 units	Duties
Coal Handling			
Coal foreman	1	1	In charge of coal handling to bunker.
Coal-conveyer operators	2	2	Operate crushers and conveyer system.
Coal laborers	2	2	Dump coal cars.
Ash Handling			
Crane operator	1	1	Operates locomotive crane in assisting to distribute ash; part time only.
Locomotive operator	1	1	Operates dinky locomotive in shunting coal cars; part time only.
Laborers	2	3	Load ashes to cars.
Miscellaneous			
Coal and ash sampler	1	1	Takes and mixes samples, etc.
Boiler Maintenance			
Boiler-repair man	2	3	Repair leaks, clean inside of tubes, etc.
Boiler-repair-man helper	1	2	
Stoker-repair man	2	2	Repair and overhaul stokers.
Stoker-repair-man helper	2	2	
Bricklayer	1	1	Repair brickwork.
Bricklayer helper	1	2	
Furnace cleaners	2	2	Clean slag from tubes, etc.
Soot-Blower Maintenance			
Pipe-fitter	1	1	Repair soot blowers.
Pipe-fitter helper	1	1	

TABLE 6 SUMMARY OF BOILER DATA—DECEMBER, 1921—COLFAX POWER STATION

Boiler No.	Lb. Water Evaporated	Lb. Coal Consumed	Hours Active	Effici'y per cent.	Rating per cent.	Exit Gas Temp., deg. fahr.	CO^2 per cent.	Combust in refuse per cent.

8	70,546,000	7,761,900	640	77.0	171	481	11.0	27.18
Total	442,550,000	48,790,580	4038	76.8	176	478	11.2	26.99

Average superheat, 132 deg. fahr.
Average feed temperature, 193 deg. fahr.
Average B.t.u. in coal, 13,283 per lb.

180 deg., but 145 deg. has seldom been exceeded. The boilers to be installed this summer will have the superheaters located above the sixth row of tubes, and with this arrangement no trouble from deficient superheat is anticipated.

There is one forced-draft fan for every four boilers. The fans are of the radial-flow type, and have a capacity of 250,000 cu. ft. of free air per minute at a maximum static pressure of 6 in. of water. The fans are driven through reduction gears by 420-h.p. turbines. Each fan engine is provided with a speed controller actuated by variations of steam pressure in the main header. Ordinarily no control of the stoker air other than that provided by the automatic, forced-draft-fan speed control is used, although individual wind-box dampers are provided that may be used in case of emergency. There is one main forced-draft duct, 9 ft. 6 in. by 15 ft., running beneath the firing-aisle floor, from which all stokers are supplied. This duct is provided with sectionalzing dampers located midway between the fan inlets. At each boiler a branch duct runs from the main duct to the stoker wind boxes. The duct system is of 3/16 in. sheet steel made practically airtight without welding.

The generator-cooling-air discharge is carried to the main air-supply duct from which the fans take part of their supply. In addition to this, large openings are provided at the tops of the fan chambers through which air may be drawn from the top of the auxiliary bay. In winter the openings between the fan chambers and the boiler-room basement are closed. This is done to prevent freezing of piping due to drawing large quantities of air from outdoors through the boiler-room basement.

Fig. 5 shows the hourly variation in boiler-room operation over a typical 24-hr. period. Fig. 6 shows the average efficiency, rating and gas temperature for all boilers for the period from July 1921 to February, 1922. This clearly shows the steady increase in efficiency as conditions were improved and as the operating force became more familiar with the equipment. The low point at the beginning of December was due to a period during which there was considerable trouble with clinker.

Piping System

The piping system for boiler feeding consists of a main and auxiliary header. The main header runs below the firing-aisle floor and between it and the forced-draft duct. A feed line is carried up each side of the boiler (these boilers are provided with feed connections at both ends of the drums) and is controlled by globe valves at the boiler-room floor level. Automatic boiler-feed regulators are provided on the feed lines at the boiler drums, part being Stets and part Copes regulators. The auxiliary header runs over and at the rear of the boilers. The auxiliary feed line on one side of each boiler is provided with a by-pass through the automatic

controller, that on the other side being provided with hand control only. The boiler feed system in general is described below.

The piping system was installed in accordance with the general piping specification given in the complete paper.

Feedwater System

The feedwater cycle is shown diagrammatically in Fig. 7. All water in the system is distilled. Make-up water is provided by two evaporators of the double-effect, dry-tube type. Water from the evaporators is pumped directly to the head tanks, above the barometric condensers, which serve as feedwater heaters. The average make-up required is about 19 per cent of the total amount flowing in the system. The tail pipe of the barometric condenser is sealed in the boiler-feed tank from which the feed pumps take their action. Two V-notch meters are provided in this tank; one measures the water going to the feed pump and the other the overflow. All overflow from the system is piped to the boiler-feed tank so that it is recorded by this meter. Overflow from the boiler-feed tank flows to the main storage tank mentioned below. There is some variation between the water quantities recorded by the venturi and V-notch meters, but it is the venturimeter readings which have been used as a basis for all results given in this paper.

There are three 4-stage 1,500-g.p.m. turbine-driven centrifugal boiler-feed pumps, regulated to maintain a pressure in the feed system of 350 lb. per sq. in. One pump is sufficient to supply the total feedwater for a load of about 60,000 kw.

Condensate from the main unit goes first to a surface heater where its temperature is raised about 4.5 deg. fahr. by the transformer and turbine-oil cooling water. It then goes to the evaporator condenser serving there as a circulating medium, and its temperature is increased about 32 deg. fahr. From the evaporator condenser it goes to the head tank and then through the barometric condenser. The exhaust from the house turbine and that part of the exhaust from the auxiliaries which is not used in the evaporators is here condensed, bringing the temperature of the mixture to about 205 deg. fahr.

The storage tank employed has a capacity of 200,000 gal. and serves to take up fluctuations in the demand for feedwater and to provide a reserve supply for emergencies.

The evaporators have in general given satisfactory service. They are so connected that either river or deep-well water may be used. The river water, although very dirty, was found to contain less scale-forming salts than that from the wells, and is therefore generally used. The effects are reversed every four hours, thus minimizing scale formation. The terminal efficiency of the evaporators is practically 100 per cent., and with the modifications now being made it is thought they will give no trouble.

Water qualities throughout the cycle are closely watched. a multiple-point, indicating conductivity meter with cells

Ashpit loss	482	3.66	558	4.23	490	3.69	479	3.64
Heat accounted for	13,059	99.24	12,930	97.96	12,814	96.47	12,810	97.21
Heat unaccounted for	100	0.76	268	2.04	469	3.53	367	2.97
Total	13,159	100.00	13,198	100.00	13,283	100.00	13,177	100.00

located at various points is used to observe the water purity continuously. This instrument immediately indicates leakage of circulating water into the condenser and permits a close check in the quality of the distillate from the evaporator. No condenser leakage has as yet been detected, but much useful information on the performance of the evaporators has been obtained.

It has been found that dissolved oxygen in the feedwater tends to pit the boiler drums. It has also been determined that this pitting takes place during banked periods, there being practically none when the boiler is active. In order to decrease the quantity of dissolved oxygen to the lowest possible point, all parts of the feed cycle are effectually sealed against air. The feed temperature is maintained at 205 deg. or higher to drive out the entrained air. Further experiments are being carried on to determine whether a lower feed temperature with a higher vacuum in the barometric condenser will improve this condition.

Figure 8 shows the relation between temperature and oxygen content as observed at Colfax. Table 3 gives the results of observations of dissolved oxygen in the boiler feedwater taken from the condensate-head tank and the boiler-feed tank.

Tables 4 and 5 show the personnel of the boiler-room organization with one unit as at present, and as it will be when a second unit is installed.

Table 6 is a summary of boiler-room operations for the month of December, and table 7 a recapitulation for the six months, August to January, inclusive.

The heat balance for the station is worked out daily. Table 8 shows the averages of the heat balance figures for the months of October to January, inclusive.

Conclusions

In considering the results given in the paper the following points should be borne in mind:

(a) The operating results given are from the records of the operating department of the Duquesne Light Company.

(b) The plant is not equipped with heat-reclamation equipment such as economizers or air preheaters.

(c) The efficiencies given are not test results but have been made with the regular operating force and can be maintained year after year. The results are good but do not represent the best performance possible with the equipment. Some further improvement is expected as the operating force becomes more familiar with the equipment.

(d) The amount of combustible in the ash is high, but as explained above, the necessity for early quenching of the ash to prevent clinker makes improvement in this respect doubtful. In the light of over-all efficiency the slight excess in combustible is a lesser loss than the formation of hard clinker masses would occasion.

BOOK REVIEW

We have received from the publishers, Chapman & Hall, Henrietta Street, London, a book on boiler-testing, written by Mr. David Brownlie, B. Sc., (London), and a member of a number of the professional societies. The first half of the book is devoted to results being obtained at present in Great Britain, and by reason of the very wide range in types of boilers and plants covered, running into the hundreds, the figures are very valuable. Mr. Brownlie has condensed the result of hundreds of tests to an average performance, and it proves beyond doubt what many of us have always felt, that the average performance is extremely poor. Following this Mr. Brownlie criticises the present codes in existence for testing boilers, and not content with mere criticism he suggests new features which may be added to an international code as a result of further investigation.

Mr. Brownlie thinks the code of the A. S.M.E. is far better than the code of the Institution of Civil Engineers in use in England, but he is not satisfied with their revised code in all particulars. He thinks that the time is ripe for an international code, to be drawn up by the British, French, and American engineering societies and scientific societies working together.

This book from the pen of a man who has wide experience in the actual testing, and tabulation of results of so many different tests, will give food for reflection to those interested in getting at the real performance of boiler plants. The criticisms he makes are of a practical nature and so are the suggestions for changes. Altogether, it is a book of great value to the consulting or testing engineer, and to those in charge of large plants who make daily run tabulations. The book is ten shillings and sixpence in London.

FUELS FOR WATER GAS MANUFACTURE

A series of tests on the use of mixtures of coal and coke in the manufacture of water gas is planned by the Bureau of Mines, to be conducted at plants at Davenport, Iowa; Ottawa, Illinois; and Beloit, Wisconsin. Wilson J. Dunkley, gas engineer, of the Urbana, Ill., station, will conduct the tests.

PREPARATION OF COAL STUDIED

At the Central District experiment station of the Bureau of Mines, Urbana, Illinois, in the course of a general study of the preparation of coal, Thomas Fraser, assistant mining engineer, has completed experiments on the determination of the minimum sliding angles of different coals on steel. A study of the general subject of coal screening is being made at this station.

EQUIPMENT FOR BURNING LIGNITE CHAR.

In the course of the experiments being conducted by the Bureau of Mines at Pittsburgh, Pa., looking toward the development of grates and furnaces to enable lignite char to be used for domestic purposes, a sheet iron grate for use in base burner stoves has been designed which permits lignite char to be burned in such stoves in place of anthracite. The development is of interest in connection with the problem of commercial utilization of the vast lignite deposits of the Northwest.

AN ANNOUNCEMENT

The Taylor Instrument Co. of Rochester, N. Y., have purchased the building at the corner of Church Street and Lombard Street, Toronto, formerly known as the Stevenson Building, but now to be called the "Tycos" building. The Taylor Company are carrying on assembling and repair work in the Toronto factory at the present time, and for the moment they will confine themselves to this work. The extent to which the company will manufacture or assemble the various instruments comprising their well known lines, will depend entirely on the Canadian demand.

Practical Electricity for the Power Plant Engineer

By G. R. ARCHDEACON, A.M.I.E.E.

CHAPTER VI.

OWING TO THE rapidly increasing use of Storage Batteries for such purposes as starting the Auxiliary gasoline driven fire pump in the local water works, fire a arm systems in factories, automatic te ephone systems, in warehouses and departmental stores, it has now become imperative that the engineer should devote a little of his time in acquiring a sound working knowledge of the underlying principles governing the operation and care of storage batteries.

It is a well known fact, that there is nothing employed in the modern Power Plant that is so little understood, and so much abused as the storage battery.

All other pieces of apparatus in the power house quickly resent ill-treatment and soon give audible evidence of such resentment, whereas the storage battery, hidden in a p ain "black box of mystery" or contained in its glass jar, refuses to "squeak" or "groan" or "hammer." Hence it is all too frequently assumed that "all is wel with the child."

Of all the machines in the power house the storage battery is the one that responds in the most generous manner to the proper care and attention, as no other machine can supply the amount of overload as the storage battery. The storage battery is often called upon to supply 200 or even 300 per cent. overload. And never fails to respond if in proper condition.

Before we can approach the underlying principle of the storage battery it is necessary to obtain a grasp of the principles of electrolysis.

Electrolysis

When a D.C. current passes through any non-metallic liquid which has electrical conductivity, chemica action takes place. The fluid is decomposed and split up into its original elements.

For such reasons it is always necessary to add a small percentage of salt, or sulphuric acid to a tank of water through which you desire to send a current of electricity, as frequently arises when it is necessary to erect some form of water resistance.

The higher the percentage of salt or acid added to the water, the lower will be the resistance of the water, with a consequent increase in its conductivity.

In sending a current of electricity through the chosen liqquid the end of the positive wire is inserted into the solution at one side of the tank, and the end of the negative wire is inserted at the other side of the tank. Care must be taken to see that they do not touch together, or it would result in a "short circuit."

We now speak of these two wires as electrodes, or poles, and they are given special names, which must now be learned off by heart. That part which is immersed in the liquid is called anode or cathode according to whether it is connected to the positive pole or the negative pole.

The wire connected to the positive pole of the dynamo, is known as the anode.

The wire connected to the negative pole of the dynamo is known as the cathode.

The current flows from the positive pole of the dynamo to the anode, leaves the anode to pass into the liquid flows through the liquid to the cathode. It then leaves the liquid, travels up the cathode out of the liquid and then back to the dynamo along the negative wire.

The chemical action only takes place at the points just where the current leaves the anode to enter the liquid, and just where the current enters the cathode, as it leaves the liquid.

No chemical action occurs in any other part of the electrolyte.

This restricted area of operations is due to the action of the ions. These ions are the carriers of the electricity through the electrolyte. They are supposed to be groups of atoms, which are charged either positively or negatively and move in a continuous procession through the electrolyte.

Those ions who carry a negative charge, are called anions.

Those ions who carry a positive charge, are called cations.

The negatively charged anions pass in a direction opposite to the current flow, going towards the anode, and there give up, the charge being neutralised by the positive charge of the anode.

The positively charged cations pass in the same direction as the current flow, flowing towards the cathode, and there give up, the charge being neutralised by the negative charge of the cathode.

Put in a concise form an ion is merely an atom or group of atoms charged with a certain quantity of electricity, which it tranfers from one electrode to another.

From this it will be apparent that there is actually no "direction of current flow," as this is absolutely a matter of the ions taking on their respective charges, and transferring these charges between the anode and the cathode.

The usual products of electrolysis of weak solutions of acid and water (remembering water in a pure condition will not conduct the current) are oxygen and hydrogen.

The oxygen appears at the anode, and the hydrogen appears at the cathode.

The quantities of oxygen and hydrogen formed by the passage of a current of D. C. electricity through slightly acidulated water is always in the same proportion, viz.:

Eight times as much of oxygen as of hydrogen by weight.

Twice as much hydrogen as oxygen volume.

These proportions being nature's fixed limits for the proportions of these gases when combined to form water, or what is expressed chemically as H_2O.

Whenever chemical dissociation is produced, energy is required.

The energy necessary being proportional to the amount of heat set free when the compound was formed by the

combination of its constituent molecules.

Conversely, when chemicals in an electrolyte combine to form a new substance, the heat energy of formation may manifest itself as electrical energy instead of heat.

This fact makes possible the electric battery.

Let us now briefly review the laws laid down by Michael Farady (an Englishman) who established the principal laws controlling electro-chemical action.

(1) The amount of substance liberated at an electrode is proportional to the amount of electricity passed through the cell.

(2) The amount of each element deposited by unit quantity of electricity is a definite and constant quantity, which is termed the electro-chemical equivalent of the element so deposited.

(3) If the same quantity of electricity be passed through different electrolytes, the weights of the different substances deposited, will be proportional to their respective electro-chemical equivalents.

These laws can be expressed as follows:

Let Z = Electro-chemical equivalent.

Let Q = No. of coulombs of electricity.

Let c=Amperes flowing in the circuit.

Let t = Time in seconds.

Let W = Weight of substance deposited in grams.

Then W = Z x Q.

Whilst for a steady passage of current of C amperes for t seconds

Q = c x t

W = Z x c x t.

The electro-chemical equivalent of a substance is the ratio of quantity, by weight of the substance which is decomposed by one coulomb of electricity, to the quantity of hydrogen liberated by the passage of one coulomb.

Numerically this is supposed to be equal to the atomic weight of the substance divided by its valency.

Hydrogen being the lightest gas is taken as the standard, both in regard to its atomic weight, and its valency. It is therefore regarded as unity, or equal to one. Therefore its electro-chemical equivalent must be also unity.

The following table gives the electro-chemical equivalents of a few of the principal elements.

Element	Electro-Chemical Equivalent
Aluminum	0.0000936
Copper, (cupric)	0.0003281
Iron, (ferrous)	0.0002902
Lead	0.0010716
Mercury	0.0010374
Nickel	0.0003043
Sodium	0.0002388
Silver	0.0011181
Tin	0.0006116
Zinc	0.0003370
Gold	0.0006791
Hydrogen	0.0000104
Oxygen	0.0000823
Nitrogen	0.0000485

It is interesting to pause here and take note of the electro-chemical equivalent of silver, 0.0011181.

Upon turning back through this series of articles, there will be found on Page 40 of Feb. 20th issue a list of practical Definitions, the first definition being that of the Ampere. Let us therefore repeat this definition.

The Ampere is the unvarying electric current which when passed through a solution of Silver Nitrate of particular strength deposits Silver at the rate of 0.0011181. Gram per Second.

Remembering that one Ampere per Second is equal to one Coulomb it will be apparent upon again carefully reading the definition of the Electro-Chemical Equivalent that this fact is proved beyond question.

If two suitable metal plates are interposed in an electric circuit and are placed a short distance apart in a liquid which is a chemical compound, the current flowing in the circuit will cause the liquid to be split up into its component parts.

If the constituents of the liquid are gases, one gas will be given off at one plate, and another gas will be given off at the opposite plate.

If one of the constituents of the liquid is a metal(as with Copper Sulphate, or Silver Nitrate Solutions) this metal will be deposited on one of the plates. This plate is called the **Cathode**, whilst the other plate is called the **Anode.**

The solution is called the electrolyte, and the process is known as Electrolysis.

Volta (an Italian) discovered in 1790 that if electrodes of two chemically dissimilar conducting materials are immersed in an electrolyte, which can attack one or both of the electrodes, an electromotive force is produced. This naturally results in a flow of current when the external circuit between the electrodes is closed.

Whilst the circuit remains open little chemical decomposition takes place. When the external circuit is closed, a flow of electricity takes place, and the chemical action becomes violent, and the attackable electrode is either gradually eaten away, being dissolved in the electrolyte, or it combines with the electrolyte to form another substance.

Volta found the amount of the electrode destroyed or converted was proportional to the quantity of electricity which was taken from the cell.

Any two chemical dissimilar electrodes which give rise to an electromotive Force when immersed in an electrolyte are called a Voltaic couple.

There are two different classes of Voltaic Couples—

(a) Chemical electrodes which give an electromotive force, until the chemicals are exhausted, and then have to be discarded.

(b) Chemical electrodes which are not exhausted or dissolved, but undergo certain definite chemical change until a limit of such change is reached. After which they can be returned to their original condition by sending a current of electricity through them in the opposite direction.

Any Voltaic Couple which is capable of functioning under the conditions mentioned in—

(a) is known as a primary battery.

(b) is known as a secondary battery or storage battery.

We are now in a position to fully consider the phenomenon of the so called storage battery. Strictly speaking this term storage battery is incorrect, because the battery in queston does not actually "store up" electricity in a similar manner that water can be"stored up" in a tank, and by the simple process of opening a valve take out of "storage" so much water.

The laws of electrolysis control the functioning of the so-called storage battery, and we have shown it is necessary to establish a positive charge upon certain hydrogen ions, and a negative charge on another set of ions, and that it is entirely due to the interchange between these ions that the electric current is caused to flow.

It is therefore obvious that we do not put so many amperes into a battery, and store them there like so much water in a tank. This is a question of energy transformation, rather than storage.

In this instance we have transformed electrical energy, into chemical energy, and if we reflect on this particular transformation we will realise that we have got back to the starting point.

The heat energy of the burning coal is changed into the kinetic energy of the steam engine turning the dynamo, the kinetic energy of the steam engine into the electrical energy of the dynamo, the electrical energy of the dynamo into the chemical energy of the storage battery.

As the heat energy released in the combustion of the coal is due to chemical energy, we once again demonstrate the old truth "you cannot create or destroy matter."

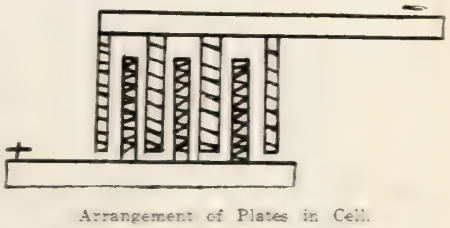
COMPONENT PARTS OF A STORAGE BATTERY

The Lead Acid Storage battery always consists of a set of Positive plates, and a set of Negative plates.

The Positive plates are usually when healthy a dark chocolate colour.

The Negative plates are a fairly light slate gray colour.

Both plates are immersed in a dilute



Arrangement of Plates in Cell.

solution of sulphuric acid and distilled water.

The plates are joined up into Positive and Negative groups.

Suggested Special Certificates

WE REFERRED in our last issue to a protest made by the Ottawa Lodge of the C.A.S.E. anent the issuing of special certificates. We expressed the view at that time, based on the meagre information at hand, that the engineers were perhaps becoming unduly alarmed. Since then, we have had more complete information on the matter, and we find that the issuing of these so-called special certificates would be in the interest, instead of against the interests, of the stationary engineers of Ontario. To begin with, we are informed that absolutely no action has yet been taken in this matter, it having not yet passed the stage of a suggestion. In order that readers may see just exactly what the suggestion embodies we are reproducing it here in its entirety. It will be seen that the measure is designed to fit the case of those small industries where the use of the boiler is seasonal, and the employment of a regular engineer would be impossible from the commercial standpoint. In these small industries there is usually a man employed in some other part of the business, who on occasion takes charge of the boiler. The special certificate will enable this man to continue to take charge, providing he can satisfy the examiners that he is a responsible man and has sufficient knowledge to operate the boiler safely. What it will not do, is to allow him to go to any other plant and pose as a certificated engineer. The certificate is nothing more or less than a temporary permit, to operate a specified plant for a stated period.

In our opinion, it is a common sense way of getting over a question of considerable difficulty. These jobs are not ones that the engineer who is making stationary engineering his regular profession would want to take, as they probably last only from three to four months during the year. On the other hand, there is nothing to prevent the certificated engineer from taking such a job if he wishes, at the wages such firms can afford to pay.

The issuing of the proposed certificate would enable the employer to utilize the services of the man who has probably been doing that same job for season after season, and still remain within the law. Nobody as far as we can see would be injured by the proposed certificates, and at the same time it would relieve these small industries from what might easily become a heavy burden.

A person who desires to operate a specified stationary steam plant of not over 100 h.p., when used in the operation of steam laundries, creameries, cheese factories, jam factories, greenhouses and other plants of similar nature, where not more than seven persons are employed must hold a fourth-class or third-class certificate from this Board, depending on the size of plant; or a special certificate which, upon examination, may, at the discretion of the Board, be granted. A special certificate shall not entitle the holder thereof to operate in any plant other than that which is specified on the certificate.

A candidate for examination for special certificate shall be required:

(a) To be at least 21 years of age;

(b) To take an affidavit on a form supplied by the Board, showing that he has had at least one year's operating experience, including at least six months' operating experience in the boiler room;

(c) To satisfy the board as to character and ability;

(d) To pay a fee of three dollars at the time application is made for examination. (This fee shall not be returned to the applicant should he fail to pass the examination);

(e) To answer the questions on the examination paper and secure at least sixty per cent. of the marks.

A candidate for examination for special certificate is required to possess:

A knowledge sufficient to operate with safety all boilers, engines, and other apparatus contained in the plant which he desires to operate.

Application for a special certificate or for the annual renewal of same shall not be accepted by the Board unless accompanied by a statement from a qualified boiler inspector in the employ of a boiler insurance company registered in the Department of Insurance, or a qualified boiler inspector in the permanent employ of the Ontario Government, or by an engineer who has obtained his first-class or second-class certificate since January 1st, 1920, to the effect that the boiler or boilers which applicant desires to operate has or have been inspected internally by such an inspector at least once during the year immediately previous.

New Steel Developed

STILL ANOTHER announcement has been made on the "discovery" of a new steel. In this case an actual improvement is said to have been accomplished by Mr. P. R. Kuehnrich of the Cobalt Steel Co., Sheffield. Cobalt magnet steel is the subject, and the improvement is reported to be an excellent one in making magnets for automobile magnetos. By adding 15 per cent. of cobalt in place of tungsten a magneto can be reduced to half its present size without reduction of power. Hence price reduction is forecast. Said Mr. J. F. Kayser, managing director of the company: "In the construction of telephones it is possible in every case to replace tungsten steel magnets of complicated shapes by straight bar magnets of cobalt steel of less than half the size, so that a big economy in material is introduced." Mr. Kayser added that the new metal will make it easy for motor car manufacturers to provide combined lighting and ignition sets. In this enumeration of mechanical blessings somebody has missed the fact that the incorporation of cobalt is not a recent invention in steel making. No harm will occur through waiting until something tangible is offered.

Refrigeration For The Power Plant Engineer

The Absorption Process of Refrigerating—Aqua Ammonia—General Construction and Details of Parts of the Machine, and a Few Words on the Operating Features of the Machine

THE ABSORPTION refrigeration machine, while it works on the same scientific principles as the compression machine, is materially different in its construction and method of operation.

In the absorption machine the only moving part of the machine itself, is a small ammonia pump. In a brine system there are, of course, the brine pumps, but they can hardly be considered as a part of the machine, but rather as auxiliaries.

The heat imparted to the ammonia, instead of being obtained by doing work in compressing the gas, is given direct to the ammonia in a generator, or still, and the gas is, instead of being condensed to liquid ammonia, absorbed in a weak solution of aqua ammonia and converted into a strong solution of aqua ammonia, and returned to the generator. Here it is again distilled, and sent on its cycle again. Briefly, the system may be described thus: Distillation of ammonia gas from aqua ammonia in a generator or distiller. Condensation of the ammonia gas to liquid ammonia in a condenser, as in the compression machine. Liquid ammonia converted into a gas in the evaporation side of the machine, taking up the necessary heat from the objects to be cooled. Absorption of the gas by a weak solution in the absorber, making it into the original strength. Pumping from the absorber to the generator by a pump, whence the cycle is again started.

Aqua Ammonia

Aqua ammonia consists of a solution of ammonia gas in water the amount of gas in the water per cent. being measured by the Beaume scale. This scale is graduated to show the specific gravity of different liquids compared to water at the temperature of 60 degrees. The scale is marked with the necessary corrections for temperature above and below 60 degrees, and in some of the instruments, a thermometer is included. The Beaume hydrometer consists of a tube with a bulb on the bottom, and in this bulb small shot is placed for a weight. It will float in water at a certain height, and in any other liquid at a different height, depending on the specific gravity of the ilquid. The reading on the Beaume scale can be converted into specific gravity in the following way. For liquids lighter than water, 130 plus the Beaume reading, divided into 140 gives the specific gravity and for liquids heavier than water, 145 minus the Beaume reading divided into 145 gives the specific gravity. These calculations are for liquids at 60 degrees F.

The aqua ammonia supplied to absorption machines usually has a specific gravity of 15 degrees Beaume, and this corresponds to a percentage of 30.1, usually known in the trade as 29½ per cent. aqua. The actual specific gravity of this liquid is .8974, and it is shipped in drums containing from twenty to forty gallons. The aqua ammonia is put in the machine by connecting it up to the ammonia pump, and pumping it into the generator. Care must be taken not to leave the drum in a hot engine room, or in the sun, just previous to taking the plug out, as the heat will generate a pressure in the drum. The result will be that when the plug is removed, the ammonia will be blown out of the drum, with unpleasant results to anyone in the immediate neighborhood, and the loss of the ammonia.

The Generator

The generator consists of a steel cylindrical vessel, in which are steam coils, the ends of which are connected to headers on the outside of the generator. The generator must be of sufficient strength to withstand high pressures, and is usually made with an ultimate strength of about 500 lbs. per square inch. The aqua ammonia is placed in the cylinder, submerging the coils, just as the water in the h.r.t. boiler submerges the tubes.

The coils are supplied with steam, either exhaust or live steam reduced in pressure. One of the advantages of the absorption machine is that it can be run on exhaust steam where that is available. When exhaust steam is used the back pressure carried is from five to ten pounds per square inch. The steam when admitted to the coils, gives up its heat to the aqua ammonia in the generator, causing the latter to boil. The gas is thus evaporated from the water, and rises up, leavin the weak solution on the bottom. The pressure of the ammonia gas is of course raised, due to the great increase in volume and the pressure of the generator rises to 130 to 150 lbs. per square inch. The level of the liquor in the generator is maintained by the ammonia pump which is constantly pumping liquor from the absorber to the generator. The generator is also connected to the absorber by a pipe leading from the bottom of the generator to the top of the absorber. The pressure in the generator being higher than that in the absorber, forces a stream of weak liquor over to the absorber all the time. The generator is furnished with a gauge glass so that the height of the liquid can be observed at all times, and the coils kept submerged, so that all the heat can be utilised.

The ammonia gas, distilled from the aqua ammonia in the generator, rises through what is known as the analyser. This

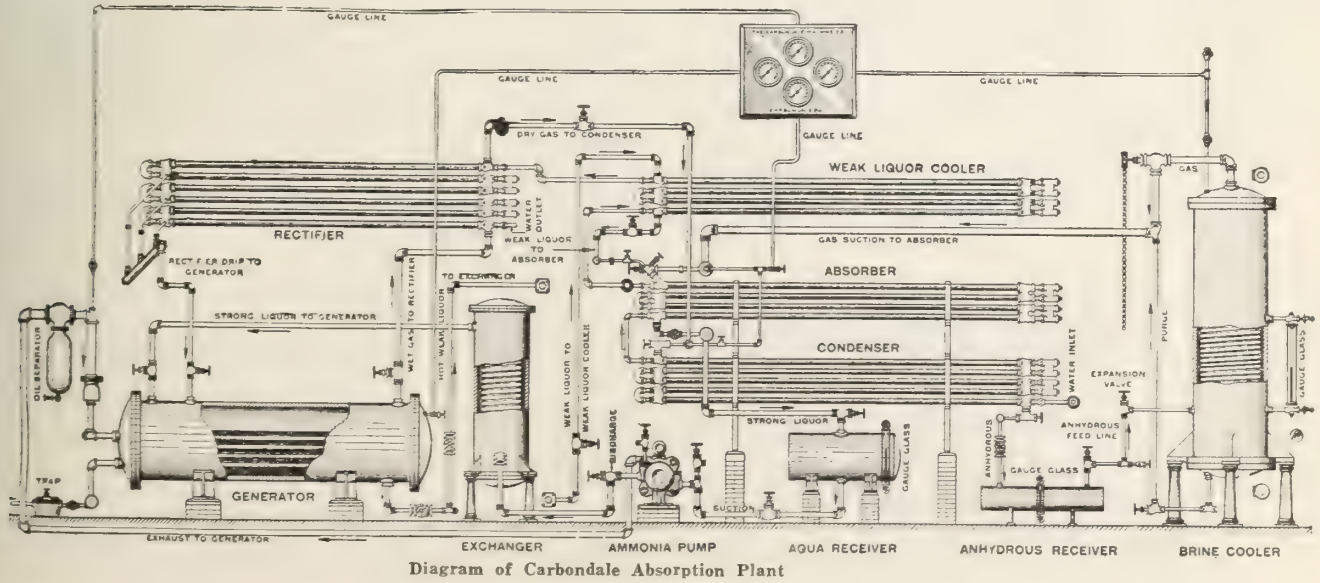

Diagram of Carbondale Absorption Plant

consists of a vertical cylindrical vessel, containing a number of shallow basins, and over these trays are suspended. The liquid returning from the aborber to the generator is introduced at the top of the analyser, and falls downward over the trays and basins, meeting the hot gas rising in its course. The hot gas gives up some of its heat to the strong liquor on its way to the generator, and at the same time any entrained moisture in the gas falls back into the basins and so back to the generator.

The Rectifier

The gas after leaving the analyser passes to the rectifier. This is a set of coils, either of the double pipe or submerged type, having just enough water circulation to condense any watery vapor there may be remaining in the gas, before it passes to the condenser. This rectifier must be kept at a temperature just sufficient to accomplish its purpose without condensing any of the dry gas. The temperature is in the neighborhood of 110 degrees. The function of the rectifier is purely to condense any vapor and leave the ammonia gas absolutely dry. The condensate returns direct to the generator. The gas is all this time on its way to the condenser where it will give up its latent heat to the circulating water, and become ammonia liquid, or rather liquid ammonia. The condenser is of the same type as those described in the previous articles, and may be of the atmospheric, or double pipe design. From the condenser the liquid ammonia is passed through the expansion valve either to the direct expansion coils, or to the brine cooler, which may be of the double pipe, or shell type as previously described. After having been evaporated and taken up the heat from the brine or rooms, as the case may be, the gas is ready to go to the absorber.

The Absorber

The absorber may be of the shell type, atmospheric type, or double pipe type. In the shell type, which may be either horizontal or vertical, the gas coming from the suction side of the machine enters at some distance from the top, directly underneath the spray from which the weak liquor from the bottom of the generator is discharged. The weak liquor, spraying down, absorbs this gas. It is necessary to use cooling water in the absorber, and this is usually done by means of tubes, through which the water after leaving the condenser is passed. The cooler the weak liquor is kept, the greater are its absorbing powers.

The Exchanger

The weak liquor coming from the bottom of the generator to the absorber is at a fairly high temperature, in the neighborhood of 200 degrees. The strong liquor coming from the bottom of the absorber is at a temperature of about 80 degrees. The heat is required in the generator but not in the absorber, so the exchanger is introduced to exchange the heat from the weak liquor to the strong liquor. This is done by means of a double pipe coil, the weak liquor flowing through one pipe, and the strong liquor through the other. These coils are arranged on the counter current system, as described previously in the articles on the compression system. The strong liquor after leaving the exchanger flows through the analyser, taking up more heat from the gas rising from the generator. It will thus be seen that all through this machine the idea is to utilize all the heat possible where it is needed by simple methods. The hot gas from the generator gives up heat to the strong liquor going to the generator, which has to be heated up by steam. The condensing water after taking up the latent heat of the ammonia gas in the condenser, is still at a temperature where it can be used in the rectifier and absorber, thus saving water.

Our illustration shows a complete plant on the absorption system as made by the Carbondale Machine Co., Carbondale, Pa. This machine is constructed entirely on the double pipe

Operation

The system after being tested out in the usual manner for leaks in the various coils, is supplied with the required amount of ammonia liquor. The generator should be filled until there is a depth of four to six inches of liquid over the steam coils, and the absorber should also have a charge of strong ammonia liquor, enough to show about half glass, in the gauge glass placed at the bottom of the absorber. This is necessary as a reservoir, for as soon as the machine is put in operation, and the gas starts going over to the condenser, the pump must be started drawing strong liquor from the absorber to the generator, and the weak liquor will be at the same time passing from the bottom of the generator to the absorber.

The first thing to do in starting an absorption machine is just the same as in a compression system, and that is to turn on the circulating water on the different parts of the system. Next turn on the steam to the generator coils, when the evaporation of the ammonia liquid will commence, and the pressure will rise on the condenser side of the system. This includes the generator, analyser, rectifier and condenser. When the pressure has reached the normal amount, which is dependent on the temperature of the condensing water and is usually from 125 to 160 lbs., the expansion valve can be opened, and the liquid admitted to the cooling coils. The valve which controls the supply of weak liquor from the generator to the absorber should now be adjusted, and the ammonia pump started, and the regulation should be such that the levels of the liquid in the generator and absorber should be kept constant.

In some cases automatic regulators are installed, which control the pump speed. If these are not fitted constant vigilance is required as the levels are constantly tending to change, and the pump must be adjusted contmually.

One of the principal points in operating the absorption machine is having a good supply of water, and the lower the temperature of this the better. If the circulating water is high in temperature, then the condenser pressure is higher, and that means that the steam pressure to be carried will have to be increased somewhat.

The absorption machine is subject to troubles from the introduction of air just as the compression machine is. However, the purging can be accomplished from the absorber, connections being fitted at the bottom and about half way up for this purpose.

The general working of the machine can be gauged by frequent testing of the strength of the liquor coming from the absorber. This should be about 26 degrees for the strong liquor and about 18 degrees for the weak liquor leaving the bottom of the generator. These proportions should remain about the same, that is if one drops the other should also drop. If the two densities approach each other it is an indication that there is a leak probably in the exchanger, so that the strong and weak liquor are being mixed.

The quality of the circulating water will determine how long the machine can run without cleaning coils. If there is much solid matter in the water, it is likely to be precipitated in the cooling coils in the absorber and condenser, and it is highly important that the absorber circulating coils in particular should be kept clean. Any rise in temperature of the ammonia liquor in the absorber reduces its capacity to absorb the gas. This means that the gas cannot pass away from the suction side as rapidly as it should, and the capacity of the machine is reduced.

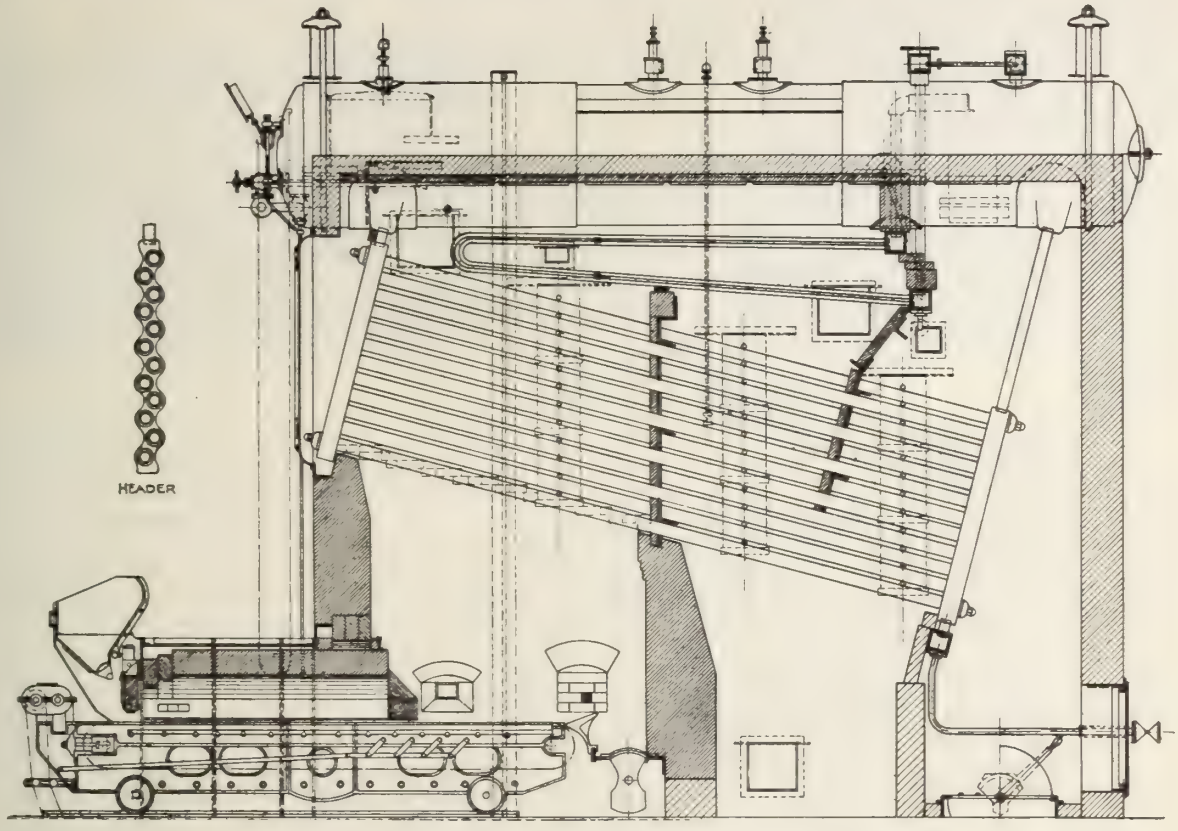
The liquid in the gauge glass on the absorber should show lots of liveliness. Dead liquid in the glass is usually a sign of foreign gases being present. The absorber should be frequently tested by the purging cocks to make sure there is no air or foreign gases present. The air will show in the usual way if the gas is discharged into a bucket of water by bubbling. Sometimes hydrogen is present in the gases, and this can be detected by opening the purge valve very slightly and applying a light to the end. If there is any hydrogen present it will light up.

In general, successful operation of an absorption machine depends on eternal vigilance even more than in the case of a compressor. Pressures and temperatures must be watched very carefully, and the levels of the liquid in absorber and generator kept constant. An absorption machine cannot be speeded up in the same manner that a compression machine can and attempts to force it lead often to trouble.

On the other hand the only moving part is the small ammonia pump, and this is usually large enough to admit of its being run very slowly. Very often these pumps are installed in duplicate so that there can be no shut down through

(Continued on page 34)

BOILER EFFICIENCY



Standard Longitudinal Drum Sectional Header Boiler

The laws of each province provide that every boiler operated within its boundaries must be built to certain recognized standards. All details such as seams, riveting, fittings, etc., must meet the approval of their inspectors before they will pass any boiler as safe to operate.

The Civil Law also states the lowest grade of engineer you can employ and how often he is required to prepare each boiler for inspection.

The lawmakers are concerned with the safety of the public, they do not make it compulsory for you to buy economical plant. You are expected, on your own judgment as a business man, to buy boilers which will give you the highest degree of safety and the greatest return for your money in pounds of water evaporated.

Now just as there are Civil Laws to make sure no unnecessary risks are taken by the public, so there are certain acknowledged engineering laws for the design and construction of economical boilers and furnaces. The success of all such equipment depends upon the success with which these laws, which safeguard your money, are applied—practically.

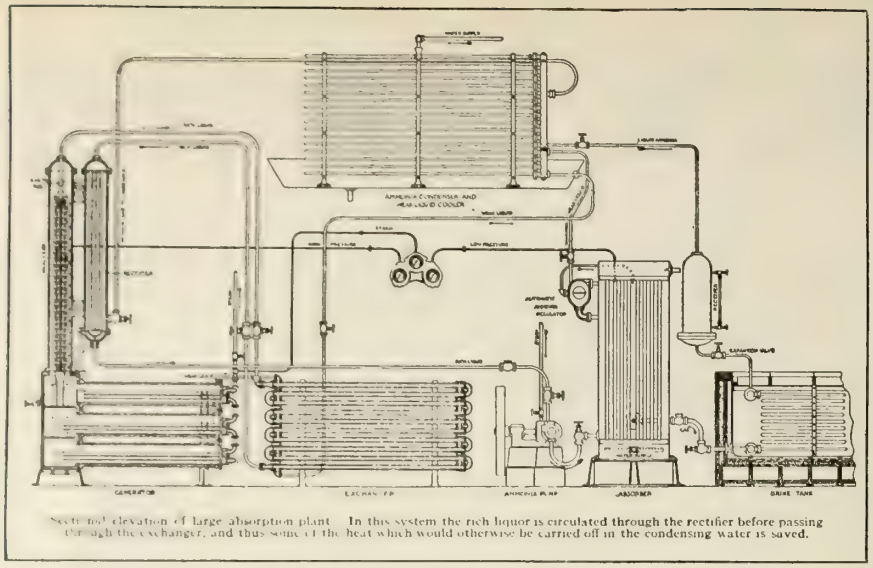
Boilers made by B. & W. are readily accepted by the authorities, even in the provinces with the stiffest requirements, because they are designed with a higher factor of safety than asked for, and no steam apparatus is made of better material or with more care. Every part is readily accessible inside and out, and with a responsible man in charge to see they are kept clean, there is little possibility of serious trouble.

As regards the efficiency of B. & W. steam plant, we can only ask you here to consider two factors—(1) THE EFFICIENT FURNACE because the fuel is fed evenly and intermixed with a proper amount of air while burning. Perfect combustion is produced and the fuel all gasified in the large combustion chamber before the heating surfaces are reached. (2) THE EFFICIENT HEATING SURFACE because of the proper circulation of the water and hot gases with reference to each other, and because they thoroughly interpenetrate each other, due to the arrangement of the baffles and the manner in which the tubes are staggered.

Babcock & Wilcox, Limited

Head Office for Canada: St. Henry, Montreal

Branch Office: Bank of Hamilton Bldg., TORONTO



Sectional elevation of large absorption plant. In this system the rich liquor is circulated through the rectifier before passing through the exchanger, and thus some of the heat which would otherwise be carried off in the condensing water is saved.

Diagram of Vogt Absorption System

REFRIGERATION FOR THE POWER PLANT ENGINEER

(Continued from page 32)

failure of the pump. If the system is a brine circulation one then the brine pumps will also be in duplicate. The exhaust steam from the pumps can be used in the generator coils. In the absorption machine heat is added to the ammonia liquid which is aborbed in the ammonia gas distilled from the liquid. Part of this heat is rejected in the rectifier, and the remainder in the condenser, but as the same water is used, it may be said to be all rejected in condenser. The heat rejected in the condenser is taken up again from the brine or room to be cooled. In the absorber meeting the gas and absorbing it develops heat, and this heat is carried away by the circulating water in the absorber coils. The principle is then the same as in any mechanical refrigerating process, that is, heat must be rejected at one part of the system and taken up at another. In the compression system the heat is added by the compression of a gas, the power required to perform this work being derived from a steam engine or a motor. In the absorption machine the heat required is derived directly from the steam, and if this steam would otherwise be allowed to escape to the atmosphere, a great economy is effected. The steam used to drive the pump can also be recovered and used in the generator. The absorption machine requires about double the amount of water that the compression machine requires, and this if water has to be purchased, is a very important factor. If a well can be bored and water secured for the cost of pumping, a great saving can be effected.

The choice between using a compression or absorption machine is one governed by conditions of location, type of plant, water supply, etc., and can only be determined for each individual installation, after considering every possible factor.

PRACTICAL ELECTRICITY

(Continued from page 29)

Only Positive plates are found in the Positive group, and Negatives in the Negative group.

Each group is burned solid to a Bus-bar, and the Pos. bus-bar is located at one side of the cell, whilst the Negative bar is on the opposite side of the cell.

Separators of either Wood, Glass Rods, or Hard Rubber are inserted between each Positive and Negative plate.

The whole is contained in either a large rectangular glass jar, or a hard wood tank lined with 3lb sheet lead, or in small hard rubber jars in case of the small portable batteries as used for automobile starting batteries.

Such are the simple parts that go to make up a storage battery yet what potentialities lay dormant within them!

The whole street car system of the City of Toronto, can be operated entirely by their storage battery plant, for a period of thirty minutes.

The large "K" class Submarines can be propelled for 300 miles when submerged, at a speed of about 12 miles per hour, entirely by their storage bat-

The Vacuum Tube on your wireless outfit depends entirely upon the storage battery for its successful operation.

Storage batteries are made in "vest pocket" sizes and increase in size until they weigh as much as 2-tons each cell.

It is important that we learn to distinguish between a "battery" and a "cell."

A "cell" is only a unit in a battery.

A "battery" is a number of cells connected together in series, so that the Voltage of each cell is added.

Composition of Plates

The composition of battery plates varies somewhat, as there are two generic types of battery plates.

(a) Plante plates.

(b) Faure plates

Gaston Plante (a Frenchman,) in 1860 discovered that by immersing two lead plates in dilute sulphuric acid, a thin skin of sulphate of lead was formed over each plate. This layer of sulphate of lead stopped all further action between the acid and the lead plate.

He then connected the plates to a D.C. source of supply and sent current through the acid.

It was then discovered that several changes took place. The sulphate of lead which had formed on the plate which was connected to the wire leading the current into the cell, was changed into Peroxide of lead, this being on the Anode.

On the opposite plate, which would be the Cathode, the sulphate of lead was changed into spongy lead.

Plante then connected these plates to a circuit through a resistance and discharged them. It was then found that the plate had once again become covered with sulphate of lead or lead sulphate.

This experiment was repeated several hundred times, and always with the same results, but it was found that as a result of continuing these Cycles of charge and discharge, the amount of lead Peroxide on the Positive plate, and the amount of Spongy lead on the Negative plate was considerably increased.

It will be obvious that such a process involves a very tedious and lengthy process of forming Lead Peroxide and Spongy lead.

If it were only possible to mechanically "coat or paste" these plates with Lead Peroxide and Spongy Lead, much time could be saved and expense reduced.

Another Frenchman, Faure, proceeded with this idea and made a skeleton framework of lead, into which he pasted the necessary Lead Oxides and achieved in a few hours what had hitherto required several months.

(To Be Continued)

Do Your Share To Prevent Fires

Every man should do his full share to prevent fires and to reduce Canada's fire loss, amounting to millions of dollars annually.

Almetl Fire Doors and Shutters will give your plant the greatest protection against the spreading of fire.

The **Almetl** is built of corrugated steel interlined with asbestos and will withstand the most intense fire without twisting or buckling.

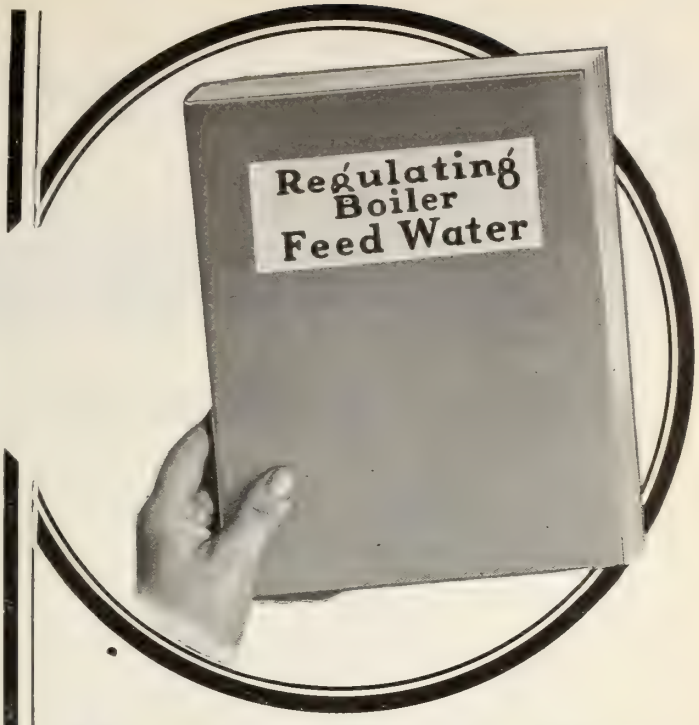
Reed's Fire-Tite oily waste cans should be in every factory, mill, power plant and garage, wherever waste is used. Built of steel, with light stork legs and self-closing lid, they are positive against spontaneous combustion fires from oily waste.

Made in three sizes.

Almetl Fire-Doors and Fire-tite oily waste cans bear the Underwriters' Label.

Write for particulars.

Geo. W. Reed & Co.
LIMITED
MONTREAL



This Free Book Shows how you can save on your fuel bill—

Our latest book—just off the press—shows how fuel savings ranging from 2% to 8% are being made in many plants, simply by improvement in feed water regulation.

The first part of this booklet, written by a prominent authority on power plant engineering, gives most excellent ideas about what feed water regulation ought to be, mechanically.

Then follow some unusual charts, showing in an interesting way the effects of different methods of water feeding on boiler efficiency.

This book will prove very helpful to any power plant engineer or manager who is interested in saving fuel, and eliminating waste. We will be glad to send you a copy, without charge or obligation.

To save your time, just write your name on the coupon, pin it to your letterhead, and mail it to us.

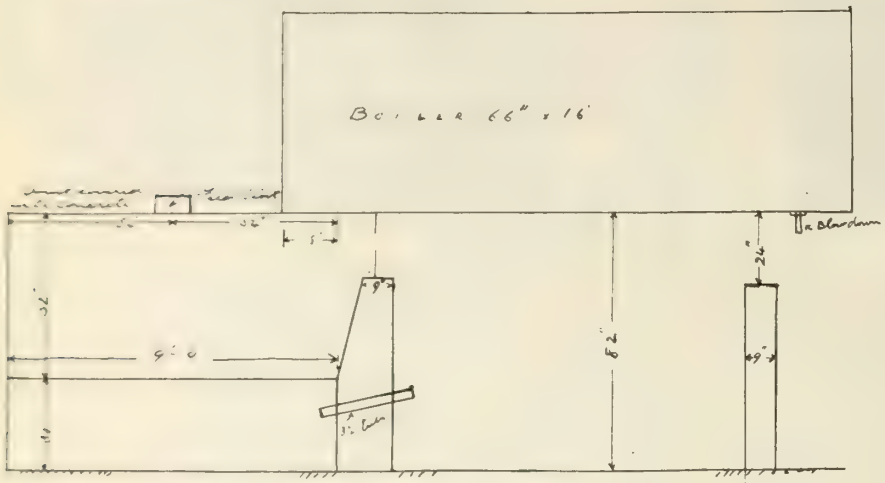
The Operators' Point of View



Outline of Dutch Oven Setting

DUTCH OVEN DESIGN

By W. H. Long

The accompanying illustration shows the Dutch oven boiler setting which I have installed in the plant of which I am in charge, and which is my own design. It is operating at 138 per cent. rating, and giving perfectly smokeless combustion.

Before the changes were made the boilers were giving 78 per cent, rated capacity, and I was given a free hand to make any change I saw fit.

On examining the boilers I found that the combustion chambers were filled with gravel, so that it was impossible to crawl under them. The bridge wall was just ten inches from the shell. The feed chutes for the sawdust, etc., were too far back. I, therefore decided to tear out the old ovens, and build new ones as shown in the sketch. The tube through the bridge wall is to carry air to the combustion chamber to complete combustion and it is a decided success. The fuel I am using is sawdust and trimmings. I would advise anyone who is using Dutch ovens to clean out combustion chamber and put in the pipe as it will help them greatly.

FILING SYSTEMS FOR ENGINEERS

Readers of Trade-Journals are often invited to send in their suggestions, as to how the publication may be made more interesting and helpful. One journal recently sent out a circular letter stating "we can get anything that our subscribers want, if we know that enough of them want it." The purpose of my letter is to explain a need or "want" of every ambitious stationary engineer, and the solution is quite within the reach of all at little expense. The publishers I think can do much to facilitate my scheme and incidentally make the publication "Power House" of greater value not only to the reader but to the advertiser; 1st by arranging the reading matter topically; 2nd, by a classified arrangement of the advertising, as far as it is practicable.

If the engineers realized the many advantages of having and keeping an "up-to-date" Topically Indexed file for handy reference, they would not be long in expressing their "want" or need; especially as same may be procured at a very moderate cost and kept up to date with very little time and effort.

The purpose of the Vertical —Indexed Topical—file suggested is to preserve articles of interest and usefulness clipped from Power House; also ads description of new apparatus or appliances. It is a peculiar fact that most engineers eagerly read all the advertisements in Power House because they are a ready source of information to the engineer who is anxious to better operating conditions in his plant. The first requisite for Topical filing is a telescopic-file, preferably a vertical one, either letter-size (8½ x 11½) or Legal-size (9x14) which the average engineer could make himself at little expense and buy re-inforced blank tabs, for the purpose of Indexing. However, there is a well known make of Vertical-telescopic indexed-files on the market which may be obtained for the purpose at $1.25 to $2.50 each depending upon the quality and size of case. Once in the possession of such a file, its value and usefulness is soon proven. A traveller calls, and hands the engineer a pamphlet on Feed-Water-Treatment (Scale and Boiler Compounds), which he promptly files under the heading of Water-Treatment; he next looks up a reference book to find a solution for the trouble he has encountered in connection with the use of boiler (H.W.) Return Traps. He then makes a sketch of the trap and its connections on a sheet of paper suitable for filing, notes what is said in the reference book as to the probable cause of the trouble (failure of check-valves to seat, etc.) and carefully files this information for future reference under the heading of Traps. In this way notes on any subject particularly those made while attending the educational meetings of the C. A. S. E. should be carefully filed; likewise information obtained from experienced engineers' descriptions of new power plant apparatus or equipment. The following general classification of subjects for Topical filing may be added to meet the requirements of each individual case.

A—Air-cooled cylinders, see engines and compressors, air-brakes, etc.

B—Boilers, boiler setting, brick work, brake test, boiler regulations.

C—Condensers, compresors, combustion, coal (origin and analysis).

D—Draft-indicators, damper-regulators and recorders.

E—Evaporation and expansion of gases, steam, etc.

F—Fuels, flame, firing vs stoking, filters and purifies, fans.

G—Grate-bars, gas engines (see internal combustion).

H—Heating (see radiation); Horse-Power equivalent, etc.

I—Internal Combustion vs. External Combustion Engines etc.

J—Judging the best kind of material or equipment, comparative.

K—Kinds of fuel, for what purpose or service each is best suited.

L.—Lubrication of cylinders and machinery—laws re.

M.—Metering pres. and flow of water, steam, elec., gas, oil, coal, etc.

N.—Natural draft vs. forced or induced and smoke prevention.

O—Oxygen (see combustion) oil and greases; overload capacities.

P.—Pumps, piston rings; pipe sizes, covering and capacities.

(Continued on page 38.)

Mr. Manufacturer—

Is this hint from a reader Worth anything to you ?

A STRIKING message to manufacturers of power-house equipment is derived from a letter written by a "Power House" reader in reply to a request for a criticism of the paper and for suggestions as to how it could be improved. In asking for criticism it was to the editorial portion of the paper rather than to the advertising that reference was intended, and there was no expectation of eliciting such a remarkable testimonial to the paper's efficiency as a medium of publicity. This spontaneous tribute should therefore have a doubly convincing effect. Here is the letter:

Circulation Manager Toronto, April 8, 1922.
Power House.

Yours of April 5, 1922, to hand asking for my candid opinion about Power House. Any opinion other than an honest one is worthless and some parts of the following may not be just to your liking but it is at any rate honest.

I believe Power House compares favorably with other power-house journals in many respects. One department I would like to see at least three times its present size is the selling section. Many of the ads. are from all-American U.S. firms but there must be many others, some of them with Canadian branches and agencies, who do not carry an advertisement in Power House. **This is a mistake on their part,** but for all I know to the contrary it may be due to the lack of energy on the part of the Power House ad. manager in getting after them. **It is an absolute fact that the engineer is more than ever dependent upon his technical journals for information in connection with new ideas in power plant equipment. He does not depend upon the reading pages SO MUCH AS ON THE ADVERTISEMENT PAGES.** I write from experience. For the past twenty years I have been first engineer in different government-owned power-plants and I have, time and again, secured ideas tending towards improved conditions in power-plant work from the selling section of Power House. The buyers' directory is good, I would like to see the advertisers index several more pages....."

Suppose you were asked—

by an engineer to tell him something about your products—you would jump at the chance, of course. Well then, do you realize that twice every month some 4,000 such men—men vitally interested in your products—are literally **asking you** to tell them something about your products. That is why these men subscribe to "Power House" (a Canadian journal devoted entirely to Power Plant Efficiency in Management, Equipment and Operation), because they want to know in just what way **your products** will benefit them. **Why don't you tell them?**

We offer you the experience of our Advertising Service Department for the preparation of your messages; in fact for everything from specific information to the planning of an entire campaign. Make use of us; but, before everything else, properly appreciate the unique value of Power House as a medium and make use of it.

POWER HOUSE

143 UNIVERSITY AVENUE **TORONTO, ONT.**

OPERATOR'S POINT OF VIEW

(Continued from page 36.)

Q.—Questions, for the educational committee of the C. A. S. E.

K.—Kinds of fuel and service each best suited for.

L.—Lubrication of cylinders and machinery—laws, etc.

M.—Meters, pres. and flow of water, steam, elec., oil, coal.

N.—Natural draft vs. forced and induced (smoke prevention).

O.—Oxygen (see combustion) oils and greases (see lubrication).

P.—Pumps, piston rings, pipe capacities and covering.

Q.—Questions referred to the educational com. of C. A. S. E.

R.—Radiation, heat insulators, radiators, refrigeration.

S.—Steam engines and turbines, steam heating.

T.—Tables and equivalents, temperature (latent and sensible heat).

U.—Uniflow—gas and steam engines, underground Ste. Mains.

V.—Ventilation—Valves, venturi, variable speed control.

W.—Water-filters and treatment, water-wheels, fly-wheels.

X.—Copies of daily boiler and engine room reports and charts.

Y.—Copies of the weekly boiler and engine room reports and charts.

Z.—Copies of the monthly boiler and engine room reports and charts.

No doubt there are more elaborate and complicated systems in use for filing subject matter, but I have tried to outline the one which I have found to be the simplest and best. Hoping the idea outlined above will be found helpful to engineers, I am

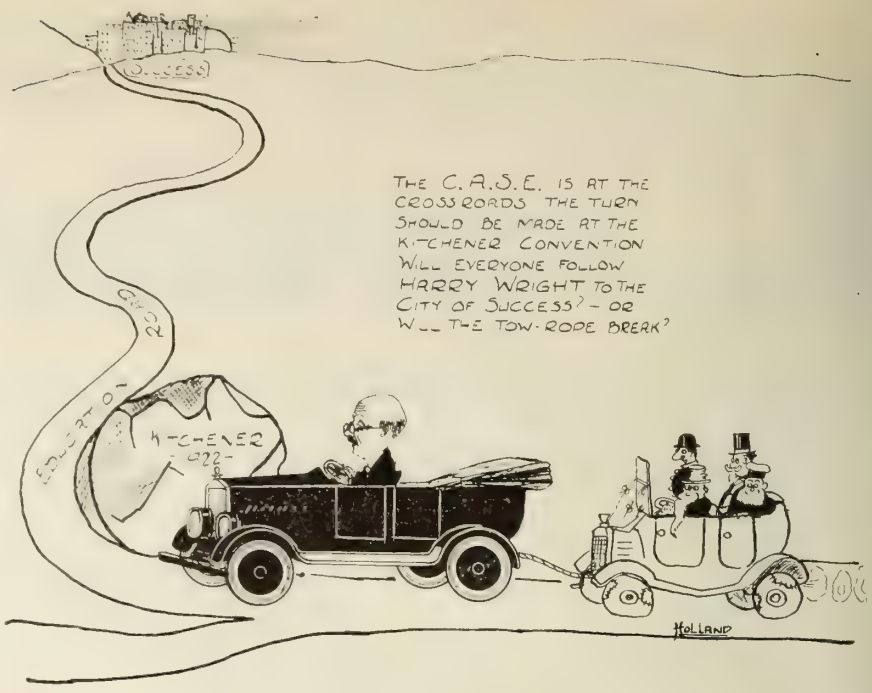
Yours truly,
Geo. J. Soucy,
(2158 Gerard st., E.)

C. A. S. E. MATTERS

The Editor, Power House:

I thank you for the space afforded my letter on the Inter-Provincial Certificate. I must ask you again for the space to comment on your Editorial Note of the coming Convention of the C. A. S. E.

I, like yourself, have seen for the last few years, that the C. A. S. E. has been lacking in leadership and organization, and that it has been trying to serve two masters. We are taught from early childhood that we cannot serve God and Mammon, so also we cannot run an Educational Society on Fraternal Society lines. You have either to co-operate with Capital or you must come out in the open and declare that you are against it, that is why, in my opinion the C. A. S. E. has been at a standstill the last ten years or more. The time has now come to modernize it and carry out the preamble to the letter, or scrap the preamble and declare you are out for the dollars and cents by force. This way never paid and will not do so in the future, if we are to get down to normal conditions again.



THE C.A.S.E. IS AT THE CROSS ROADS THE TURN SHOULD BE MADE AT THE KITCHENER CONVENTION WILL EVERYONE FOLLOW HARRY WRIGHT TO THE CITY OF SUCCESS? - OR WILL THE TOW-ROPE BREAK?
HOLLAND

The spirit of progressiveness you speak of is certainly stalking abroad, and if given the right support, its authors will certainly carry it through to a finish, but it must have undivided support, otherwise the revolutionizing falls flat, and it goes on in the old rut.

I was asked some time ago, when in front of the Canadian Manufacturers' Association, "How do you account for so small a membership after being 30 years formed." I replied very promptly that "Lack of leadership and organization and trying to combine two principles entirely opposed to each other, was the cause," and they agreed with me. The only remedy is to alter the Constitution to suit the aims, leave secrecy behind and come out in the open to educate your fellow man. This has led to contemplation of some very drastic changes at the coming convention, whether the C. A. S. E. members will have the foresight and stamina to carry it through remains to be seen. My reason for writing so plainly is, that there are a great number of engineers I will not be able to reach except through the columns of your paper, and I think that when the matter is explained to them in the proper light, they will be in a position to judge, and I know all sane and right-minded engineers will agree that both you and I are right and that a step has been taken in the right direction to bring the operating engineer to the place he rightly belongs to in the professional world.

I don't think it will be necessary to have a new charter, it can still remain the C.A.S.E. only it can be run on the lines of a purely educational society. In my different circular letters to the various lodges, I have gradually led up to that drastic step, for I was firmly convinced that it had to be approached very cautiously, otherwise the members would have looked askance at so large a proposition being suddenly thrust upon them. I think that a little more co-operation with the Western section of engineers will go a long way toward accomplishing the aims and progress of the C.A.S.E., also a little more infusion of technical engineers in its ranks. These people have been refused recognition in the past by the C.A.S.E. but the time is not so far distant when it will be necessary for this co-operation, unless our members want the association to remain an unknown quantity, as it is to-day.

Again thanking you for past favour,
HENRY WRIGHT, A.M.E.I.C.,
Vice-President of the C.A.S.E.

Editor, Power House:

Dear Sir:

In reference to your more than interesting article on the above society in "Power House," of May 20th, the writer endorses your remarks, particularly the secret society part. It is very unnecessary and takes up too much valuable time and is too formal.

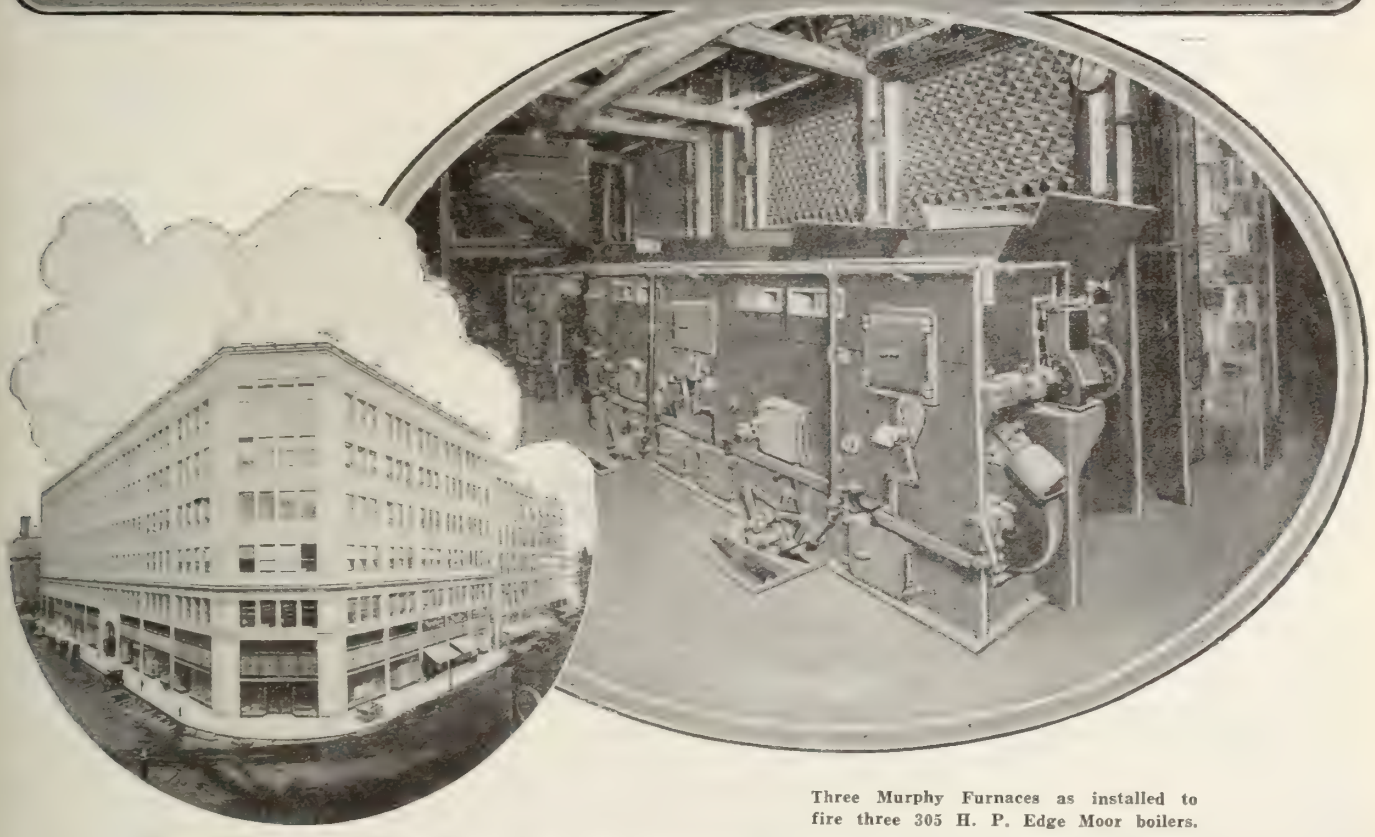
The Canadian Institute of Engineers and similar societies merely pass the minutes of previous meeting and elect members who have been ably scrutinized by the council. I would like to make a few suggestions through the columns of your influential journal as one cannot bring up a whole batch at any one meeting. Moreover it might appear to be too drastic for some. The writer has had twenty years' experience in organizing similar society work and it was our own experience from year to year, that by being affiliated with similar societies that one can make progress.

Amongst many alterations suggested for more able pens than mine to take up a few are the following:

To elect a stalwart president such as

(Continued on page 40)

221 MURPHY FURNACES
INSTALLED IN
72 OFFICE BUILDINGS



Three Murphy Furnaces as installed to fire three 305 H. P. Edge Moor boilers.

For office buildings the first requirement for stoking equipment is that it must not emit black smoke through the chimney nor obnoxious gases in the boiler room to circulate up through the building.

St. Paul's newest and finest office building, the Hamm Building—in selecting

MURPHY AUTOMATIC FURNACES

for their power purposes is assured tha t the above requirement will be met.

Here's the process that makes the Murphy smokeless. As the coal enters the furnace it rests for a short time on the coking plate. There the volatile gases are driven off and immediately mixed with the heated air admitted through the arch plate air ducts, forming a combustible gas which is burned as it passes toward the rear of the furnace. The fuel travels slowly down the inclined grates toward the clinker grinder, receiving the requisite amount of air through the grates to complete the burning process. *221 Murphy Furnaces installed in 72 office buildings, a total of 36,679 B. H. P.*, indicate that they have made *good* in this field.

If saving 15 to 30% of your coal bill interests you along with other advantages, write to-day for Catalog H-4.

(Continued from page 38)

some leading professor or some leading engineer.

A president designated.

A list of vice-presidents connected with the profession only.

A list of honorary members to be elected annually but not able to vote on direct work of the society.

If any ordinary member relinquishes his profession to be a representative he should then become an honorary member and subject to re-election.

A chairman and vice-chairman of the council where all the work of the society could be ably discussed and presented to each meeting for ratification.

Circulars should be sent to every meeting stating business. List of members' arrears, also all candidates, their proposer and seconder with all three addresses and names of firm by whom they are employed.

An annual diary should be issued gratis to every member only, giving names, address of home and their firm with telephone No. This might be done at a profit as no doubt many engineering firms would gladly take a page or more for advertisements.

More time for smoking and it would add socially if tables were used to sit around to get closer together.

A secretary and treasurer both to be paid. An assistant secretary and recorder.

A council of 7 with the secretaries and ex-officio members and the two making lowest number of attendances to ultimately drop out, but subject to re-election. Sub-committees could be arranged in the usual way but to report to council who would then report to the meetings to affiliate with similar societies and to join in their visits and excursions.

To arrange visits to cities and places of interest, say once per month in the evenings and one on Saturday afternoons and one day's excursion per year to visit large works, etc.

This need not interfere with the social rite as now carried on.

The social rite is the acme to aim for to make any society a success.

To aim at securing a room to themselves and to be open two or three nights per week, especially Saturday evenings in the winter months.

Papers should be read as far as possible by their own members.

Members should be elected similar to any other kindred societies, that is, only 1st and 2nd class engineers to be ordinary members and 3rd and 4th associates.

Ordinary members only to vote on society work.

WOODSTOCK LODGE C.A.S.E.

On Friday evening, June 8th, the members of Woodstock Lodge, No. 37, met to elect the officers for the coming year. The installation was performed by Past President Bro. Arnupp. The officers elected and installed were as follows:

President, Bro. Precious; Vice-President, Bro. G. Diron; Rec. Sec. and Treas., Bro. Geo. S. Linnell; Fin. Sec., Bro. Ross; Conductor, Bro. Angus; Doorkeeper, Bro. Meredith.

In addition to the above, Bro. Arnupp was chosen as the delegate of the lodge to attend the Grand Lodge at the Kitchener Convention.

After the business of the evening was concluded, the time was spent in social activities. The lodge looks forward to a year of great and productive activity.

INTERPROVINCIAL CERTIFICATE

Editor, Power House:

Dear Sir:

If space permits would you kindly publish the following in your valuable journal:

First, I want to thank Mr. Henry Wright for his work and timely suggestions towards the issuing of a Dominion-wide certificate for Canadian engineers.

His proposed system of issuing cards may work very satisfactory, but I would like to submit another plan which I think would simplify matters very much.

After a board of representatives of the different provinces have got together and agreed on uniform regulations, (the same as was done in the case of the inter-provincial boiler regulations) a standard form of certificate, for all grades, should be issued to every engineer, holding a provincial certificate, in exchange for his old one, the new being graded the same as his old one, and on paying of a small fee to the provincial government to cover expenses, which I think, would not exceed a dollar for each certificate.

A suggestion with reference to the certificate:

I would like to see the new certificate head-lined something like this:

CANADIAN INTER-PROVINCIAL CERTIFICATE
First-Class Stationary
Issued at
REGINA, SASKATCHEWAN, ETC.

I think the words, Canadian Inter-provincial, should appear prominently in the headlines. The grade and class such as stationary, hoisting or traction, and the place of issue, of course, to be varied in each individual case.

Such a certificate would at once be recognized by all concerned, and would do away with the more expensive card system as suggested by Mr. Wright, and of the continually issuing of cards to moving engineers. It would be less confusing to the public and to the enforcers of the law.

This plan would in no way interfere with the provincial rights or revenues of the inspection staff, as the cost of the certificate and examination in any grade would be uniform in all the provinces and all monies be paid to the respective provincial governments the same as at present

If all the provinces could not agree on uniform action at once, that should not delay the carrying out of the scheme, but as soon as two or more provinces agree it should be started.

I am convinced that it would not be long before the others would see the benefit to all concerned and soon would join.

The difference in the existing examinations in the various provinces at present, seems by some, to be held up as a barrier against the issuing of a uniform certificate, should, as Mr. Wright points out, be considered only as ground for "petty quibbling," and not be allowed to hinder the progress of the good work at all.

As to the difference in horse power allowed on second and third class certificates in different provinces, it should not be very difficult to adjust as that was only an arbitrary matter in the first place.

Now I want to thank "Power House" for its editorial stand and its liberal space given to correspondents on this question, and I hope it will continue to keep up the pressure until the desired results are obtained.

For I see in it also greater benefit to "Power House" which will then, more so than now, be a medium in which the engineers and employers from all over Canada can meet to express their respective wants.

SASKATCHEWAN ENGINEER

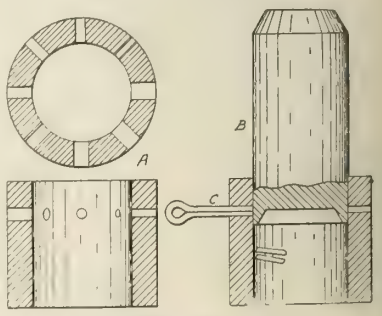
GRAPHITE AS BOILER SCALE PREVENTIVE

Tests are being made at the Southern experiment station of the Bureau of Mines, Tuscaloosa, Ala., to determine the efficacy of low grade dust from Alabama flake graphite for preventing the formation of scale in boilers.

CUTTING SPLIT PINS

By W. J. H.

The accompanying sketch shows a handy tool for cutting short pieces off split pins and small rods. The piece A is made of 2 in. cast steel bored to about 1¼ in. and having a series of different size holes drilled through the wall. These could be drilled in irregular positions if desired. The punch B is turned to fit the bore of the ring and cupped at the cutting end as shown. A light blow of a hand hammer is sufficient to cut the average split pin.



Cutting split pins

FIVE CONSIDERATIONS THAT MAKE GARLOCK NO. 900 SHEET UNQUESTIONABLY SUPERIOR

1. **Quality**—Made only of highest grade materials.
2. **Service**—Maintains a steam tight joint against the highest degree of superheat met in modern practice.
3. **Adaptability**—Is equally serviceable for air, acids and ammonia.
4. **Economy**—A joint that must be frequently opened can be remade many times, using the same gasket.
5. **Reliability**—Garlock No. 900 imprint with our trade mark is assurance of dependability.

We cut gaskets, Style No. 950, in all shapes and sizes, from Garlock No. 900 Sheet.

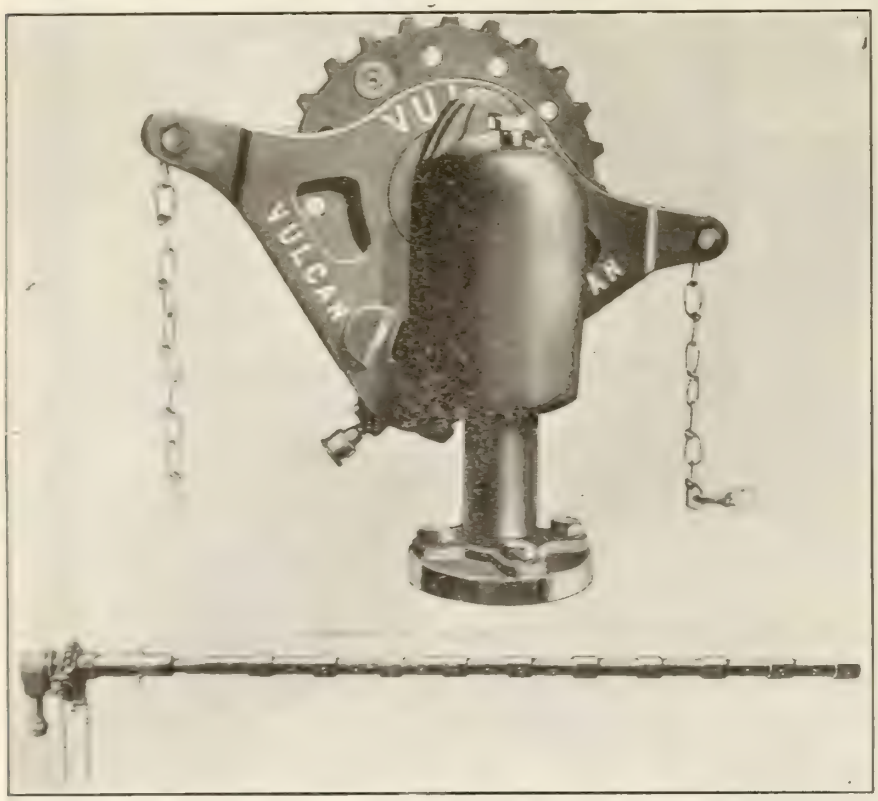
Progress in New Equipment

NEW VULCAN OPERATING HEAD

The new operating head announced by the Vulcan Soot Cleaner Company is known as the Ratchet Operating Head, illustrated in Fig. 1, the basic principle of which is automatically to limit the sweep of the soot-cleaning element, to force the operator to operate the element in a step by step movement, and hence to insure that the steam jets have an opportunity to sweep over and throughly clean every part of the tube surfaces.

For many years, a small percentage of soot-cleaner owners has complained that soot cleaners did not thoroughly remove the soot accumulations. Investigation disclosed, in a majority of these cases, that the cleaning elements either were being rotated too fast, or rotated by careless workmen through only a fraction of the full permissible sweep of the elements. As a result, the cleaner was prevented from doing its proper work, through failure to give the steam jets time enough thoroughly to clean the tube surfaces.



Vulcan Automatic Head

To correct this difficulty, to make soot-cleaner operation more mechanical and less dependent upon the efficiency of the human factor in the boiler room, the new Vulcan Ratchet Operating Head was designed and is now being placed upon the market.

The new head is so constructed that when the operator pulls the chain the element is rotated only a short distance, and can be turned no farther until the ratchet frame has been returned to its original position. Then, and only then, a pull on the chain causes the element to rotate another space. Between the lulls in operating the new head, the steam jets have an opportunity to concentrate upon a definite section of the tube surface for a length of time sufficient to insure a thorough removal of the soot. When the complete arc of rotation has been attained in one direction, which is limited by "stops" especially set for that purpose, the mechanism automatically reverses itself and the cleaning element moves back in the same manner through the same arc. Any soot that may have re-deposited after the first rotation is completely removed on the backward travel.

In designing this ratchet operating head, the Vulcan engineers kept constantly before them the fundamental purpose of every soot-cleaning apparatus, namely, to remove the soot thoroughly, and built their operating head with this purpose only in mind regardless of the competency of the individual doing the actual work of handling the equipment The net result is a device that takes the control of cleaning entirely out of the hands of the operator, and places it solely in the ratchet operating head.

The Vulcan ratchet operating head possesses five features of paramount importance to the power plant engineer. These are:

(1) It absolutely prevents the man operating it from neglecting any part of the complete sweep of the cleaning element;

(2) It substitutes a uniform rate of speed of rotation, in a step-by-step movement controlled almost entirely by the head itself, in place of the old irregular, uncertain rate controlled by the whim of the operator and his desire to get through with the job as quickly as possible;

(3) It assures a considerable saving in quantity of steam used, because the operator knows that he has to make the sweep only once in each direction and can stop when that has been completed;

(4) It provides the operator with a clearly defined task, instead of a vague and indefinite one;

(5) Above all, it entirely eliminates wrong methods of soot cleaning, and is an assurance of more satisfactory and thorough cleaning results.

The new head, as may be seen from the illustration, is remarkably simple and strong. Its action is positive and sure. There is not a part to slip out of place, and thereby throw the whole device out of action. The chain is securely riveted to the ends of the ratchet frame and no amount of pulling or jerking will tear it loose.

This new Vulcan ratchet head is operated independently of the valve. Therefore, should the element operating mechanism accidentally fail during operation the whole cleaner system is not put out of commission while repairs are being made. The value of a soot cleaner depends upon its usefulness. If the temporary failure of one cleaning element means that the whole system is out of use until that one element has beeen repaired, then, obviously, the real value of the cleaner is seriously impaired.

Fig. 2 illustrates a Vulcan sheathed

LINK-BELT

NEW EQUIPMENT

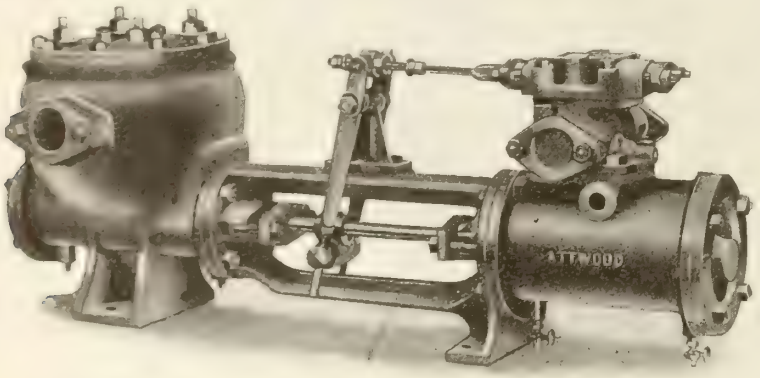
(Continued from page 42)

element, designed for a Stirling or Erie City vertical boiler, completely set up and equipped with the new ratchet operating head. The large tube between the head and the element is the wall sleeve, which is securely bricked into the boiler wall, and through the element passes to be screwed into the hub of the ratchet head. Two set screws in the ratchet wheel hub anchor the element in place.

A vitally important feature of the Vulcan element is the use of sheathing to protect the element from the high temperature gases in the first pass of water tube boilers. First comes the cleaning element itself; over it are placed short lengths of a special grade of cast iron sheathing, loose to allow for expansion; between, but overlapping the sheathing pieces, is an expansion piece, also loose; nozzles are screwed through the expansion piece directly into the element, and also, in elements designed for the Stirling type boiler, through the sheathing between the expansion pieces, as illustrated. This method of protecting elements is particularly successful in prolonging the life of elements constantly subjected to high temperatures.

THE ATTWOOD STEAM PUMP

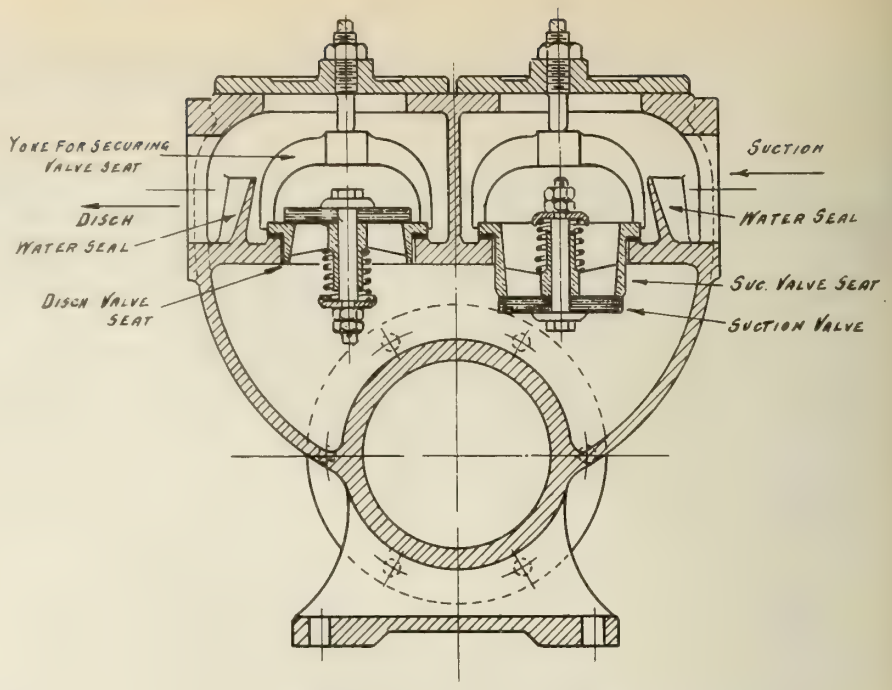
We mentioned in a recent issue of Power House that a new type of pump had been designed by Mr. Attwood of Toronto, and that we had been present at a demonstration of this pump. We are now enabled to give illustrations of this new departure, and our readers can see for themselves the construction of the water end of the pump, which differs materially from the generally accepted design.



The Attwood Pump.

There are two things in particular which are claimed for this pump, which will appeal to the operator. One is the ease with which valves can be examined and repaired, and the other is that the pump is always kept primed by reason of the suction pipe being situated above the suction valves, a seal thus being always present.

The sectional view will show how simple a matter it is to remove the valves, and seats, when repairs are necessary, such as renewing a disc or rubber valve.



Section of Water End Attwood Pump

It is claimed that the construction of the pump also makes it a much more efficient pump for vacuum purposes in connection with vacuum heating returns than the ordinary design of vacuum pump.

The direction of flow of the pump can be reversed by simply changing the suction valves over to the place occupied by the delivery, and vice versa. The design of the pump is neat, and makes for strength with a minimum of weight.

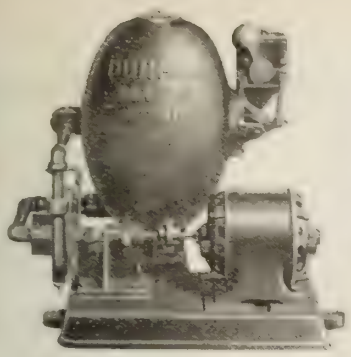
The steam end of the pump is fitted with Attwood's Improved Positive Valve Motion, which makes it impossible for the pump to short stroke under any conditions, and prevents it from stoping as long as steam is turned on. The cushioning of the piston has beeen provided for in an effective manner. The stuffing box on the piston rod has been made deep, so as to enable an ample amount of packing to be fitted, minimizing the possibility of steam leaks at this important point.

The pump is being manufactured by the Atlas Engineering Machine Works, River Street, Toronto.

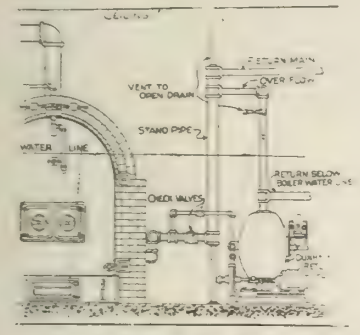
SAFETY CUP LOCK

An interesting type of safety nut lock has recently been placed on the market. The bolts used in connection with the safety cup lock are similar in every respect to standard bolts excepting that they have a square grooved end into which the tongue of the lock fastens. This square end is a decided asset because it enables the bolt to be driven clear out of the hole without the slightest injury to the thread. Highly polished, semi-finished and case hardened nuts need not be used, for the safety nut lock protects, in fact strengthens the nut considerably; therefore a plain cold punched or hot pressed nut of any standard make can be used most satisfactorily and with greater security. The cup is fastened on the square grooved end of the bolt and has no contact whatever with the threads of the bolt or the nut. It bears most of the pressure strains, instead of throwing them on the threads of the nut or bolt. The length of the cup allows considerable play for the nut, and if the nut is covered by only one-half or three-quarters of the cup, it is as firm and secure as if it were covered completely; thus the use of washers is eliminated. It is claimed that it can be used over and over again. The cup part of the safety nut lock takes the place of a jam nut, when it is desired to remove or tighten stud bolts. It can be put on and taken off very easily, without affecting the threads, bolt or nut. This nut lock is manufactured by the Interlocking Lock Washer Co. of New York.

The most satisfactory method of braking employs an electric release of the magnetic or solenoid type, as it is automatically switched in and out of circuit with the motor, any interruption to the current causing it to act insantly.



The Dunham Return Pump
Type R.L.P.



Application of the Dunham
Return Pump

The Economical Handling of Condensate

The Dunham Return Pump is an automatic, electric driven centrifugal pump that returns the condensate from heating systems or process work, back to boiler, heater, hot well or other storage.

It eliminates the waste of condensate from heating systems where returns are below the waterline. The condensate from the heating system is returned to the boiler as it accumulates, resulting in improved heating and a saving of fuel. Being electrically driven, there are none of the difficulties caused by low pressure steam pumps when fires are banked for the night. The Dunham Return Pump operates without attention day or night. It is stopped and started from a float switch.

Write for full particulars.

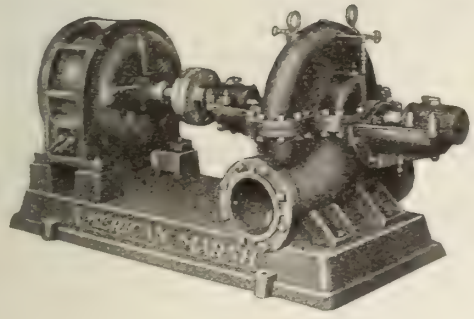
AMERICAN-MARSH PUMPS

Centrifugal and Direct Acting



Designed for use in power plants where absolute reliability and high efficiency are essential. For over thirty-five years American-Marsh Pumps have been recognized as standard throughout the Dominion. There are over 160,000 in successful operation.

The sturdy rugged construction and heavy cast bronze fittings insure long life and a minimum repair expense.

American-Marsh Centrifugal Pumps are built with the same painstaking care that characterizes the construction of the direct acting line.

The line includes:

Boiler Feed Pumps	Jet Condensers
Air Compressors	Vacuum Pumps
Deep Well Engines	Condensation Pumps
Centrifugal Pumps	Sump Pumps

Increase the Consumer's Interest

Create a Livelier Demand for Machine Shop, Power House and Foundry Equipment

ARE you manufacturing equipment for Machine Shops, Metal Working Plants, Power Plants and Foundries? Does the consumer know your products? Does he know their quality sufficiently to insist upon getting them when he places an order with his dealer? Carefully weigh these questions. Then consider the advisability of reaching the consumer through the columns of MacLean Technical Newspapers. You can probably use one of the following group.

CANADIAN MACHINERY AND MANUFACTURING NEWS—issued weekly, serving the Canadian Machinery, iron, steel and general metal-working industries: it is read by the men who buy equipment, proprietors, purchasing agents and other executives: its editorial contents are authoritative and comprehensive.

POWER HOUSE—published twice a month, serving steam, electrical, water and gas power plants, in addition to refrigeration plants, in all parts of Canada. It, too, reaches the men who buy equipment; it, too, is the leading authority of the Dominion in things pertaining to its field.

CANADIAN FOUNDRYMAN AND METAL INDUSTRY NEWS—published monthly, rendering indispensable service to the grey iron, steel and non-ferrous foundries of the country. Proprietors, executives and foremen read it diligently.

You can awaken new interest in your products by advertising them to the consumer through MacLean Technical Newspapers. Write for complete information.

Canadian Association *of* Stationary Engineers

Incorporated May, 1887
Incorporated at Ottawa June, 917

This Organization is founded on the following principles

—The better education of its members in the science of steam engineering.
—To protect the competent engineer and his vocation.
—To enroll all competent engineers in this organization.
—To impart information beneficial to the profession.
—To assist members out of employment to obtain the same.
—To procure by legal enactment greater safety in the operation of steam plants.
—The belief that knowledge and ability of one's profession is what is necessary to make success possible.

Brother Engineer:

Did it ever appeal to you to join an association devoted entirely to the interests of the engineering profession; one which by means of lectures, illustrated and otherwise, delivered in the lodge room, tends to keep its members right up to the minute with the progress made in the engineering professions?

If you are interested in an association of this kind, and live where less than fifteen engineers reside, send for a copy of our constitution, and make application to the nearest lodge for membership. If you live where more than fifteen engineers live, get together and send in a written application to me.

The undersigned will be very pleased to give any further information required.

A Striking Message

A STRIKING message to manufacturers of power-house equipment is derived from a letter written by a "Power House" reader in reply to a request for a criticism of the paper and for suggestions as to how it could be improved. Here is the letter:

"I believe Power House compares favorably with other power-house journals in many respects. One department I would like to see at least three times its present size is the selling section. Many of the ads. are from all-American U.S. firms but there must be many others, some of them with Canadian branches and agencies, who do not carry an advertisement in Power House. **This is a mistake on their part,** but for all I know to the contrary it may be due to the lack of energy on the part of the Power House ad. manager in getting after them. **It is an absolute fact that the engineer is more than ever dependent upon his technical journals for information in connection with new ideas in power plant equipment. He does not depend upon the reading pages SO MUCH AS ON THE ADVERTISEMENT PAGES."**

"Joy Shots" That Lead to Hell

By JUDGE EMILY F. MURPHY (*Janey Canuck*)

THIS IS the first of two articles in which Judge Murphy describes the menace that exists in Canada to-day in regard to the illegal traffic in narcotics. It gives actual facts from many Canadian cities and shows how the hypodermic needle is an even greater evil to combat than the opium pipe. The second of these articles will likely be in the July 15th issue.

Is Bootlegging a Passing Phase?

How common is bootlegging in Canada today? How do the members of the bootlegging profession carry on their business and what is their relationship to the officers of the law? These are two of the questions which are answered by A. Innes MacKenzie in a very colorful article describing the adventures, the fortunes and humorous rencontres of Canadian bootleggers from the Atlantic to the Pacific. Mr. MacKenzie writes whereof he knows, as he has spent several months studying this question and even associatting with many of the bootleggers themselves, in the interests of the readers of MACLEAN'S MAGAZINE.

Is the Canadian Flapper a Menace?

This is a question raised by Mrs. Gertrude S. Pringle in a startling article dealing with conditions as they too frequently exist in some Canadian centres. Extraordinary conditions are described by Mrs. Pringle, who is a thorough and conservative investigator. It is only too true, evidence regretfully shows, that some Canadian flappers are very much akin to their American sister who "parks her corsets and indulges in petting parties."

WIRELESS

The Most Fascinating Study in the World

This is the Wireless age. No longer is this miracle means of communication used only to send out S.O.S. messages of distress.

Wouldn't you like to become a wireless expert? Wouldn't you like to "listen in" on the world's news—to be close to history in the making? You can!

The International Correspondence Schools will teach you everything you need to know about wireless. You can learn at home—quickly and easily—in an hour a day of the spare time that now goes to waste.

And you will not only learn the code and how to receive and send—but you will learn how to construct and install your own apparatus.

This is all:—Just ask us to send you complete details of the I.C.S. Radio Operator's Course.

Made in Canada

Our pivoted-block Thrust Bearings are a complete solution of all thrust-bearing problems in hydro-electric units, steam turbines, ships' propeller shafts, centrifugal pumps, and similar work involving heavy loads and high or low speed.

Maximum Durability and Reliability.
Lowest possible Friction.
No limit to loads or speeds.

Protected by numerous Canadian Patents. Complete manufacturing facilities in Canada, insuring prompt deliveries and service.

Send for Catalogue.

Kingsbury Machine Works
Frankford, Philadelphia, Pa.

LADD WATER TUBE BOILERS

are to-day giving satisfactory service not only in the largest power plants throughout the country, but also in the smaller unit field where the permanent economy feature cannot be overlooked.

Our engineering department is always at your disposal.

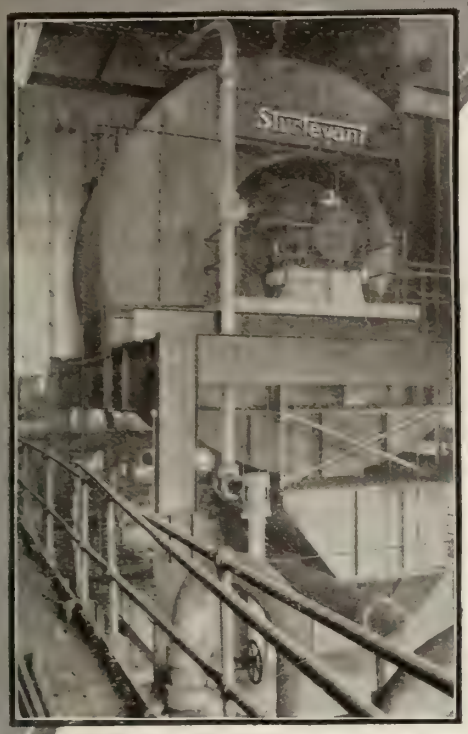
PUMPS

We stand behind our product with a guarantee that protects you fully.

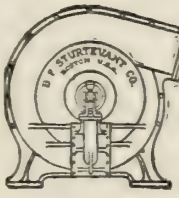
The Smart-Turner Machine Co., Ltd.
Hamilton - - Canada



Installation in Fitchburg Electric Light Co., Fitchburg, Mass. Cinders are diverted to a hopper before reaching the stack. A good, needful draft is also induced.

Keep the Good-will of Your Neighbors

It's a valuable asset to you. You may send out frequent good-will notices and give the greatest possible service to your Community. But nothing will "kill" you quicker than sending out cinders all over the neighborhood. You can easily prevent this with a



Sturtevant

PUTS AIR TO WORK

Cinder Eliminating Fan

Not only does this cinder separator eliminate the cinder nuisance, but it also furnishes a most efficient induced draft.

It is the only unit made that performs both these functions — thoroughly and satisfactorily. Write us — there is an installation in your vicinity you would like to look over.

Rotating member of the cinder eliminating induced draft fan.

POWER HOUSE BUYERS' DIRECTORY

If what you want is not listed here write us, and we will tell you where to get it. Let us suggest that you consult also the advertisers' index facing the inside back cover, after having secured advertisers' names from this directory. The information you desire may be found in the advertising pages. This department is maintained for the benefit and convenience of our readers. The insertion of our advertisers' names under proper headings is gladly undertaken, but does not become part of an advertising contract. Readers are requested to advise the publishers regarding any equipment that they are buying and that is not listed.

A Mallet and Trowel

AND A SUPPLY of Betson Plastic Fire Brick make the most durable boiler furnace lining, because it is all in one piece, free from cracks, seams, joints, moulded brick and fire clay. Shipped either mixed ready for use, or dry to mix with water (the cost is the same) from our warehouses in principal cities.

How to obtain Greater Efficiency, more power from the fuel burned, and how to save about 50 per cent. on repair and upkeep costs are told in our booklet. Send for a free copy.

PLASTIC FIRE BRICK

HEPBURN
Steam Pumps

Packed Piston Type for Medium Pressures

This patent pump is intended for Tank and General Service purposes. On such work it gives exceptional service due to the long regular strokes, accessible valves, self-draining feature and absence of all tappets or levers. It is worthy of note that the self-draining cylinders, exclusive with Hepburn Pumps, are an important factor in saving steam.

Before you purchase Pumps, Vertical Engines, Cranes, Power Presses, or castings, talk it over with us.

JOHN T. HEPBURN, LIMITED

The Highest Grade Machinery and Supplies

The leading manufacturers of each line of machinery and machine supplies are represented by Canadian Fairbanks-Morse.

To buy from the nearest Fairbanks-Morse branch is to be assured of the dependable quality that is invariably associated with such well known products.

Here Are Some of the well-known Lines we Handle:

Fairbanks Scales	Fairbanks Valves
Pratt & Cady Valves	Durabla Packing
Palmetto Packing	Foster Regulators
Strong Steam Traps	Fairbanks-Morse Gas and Oil Engines
Allen Engines	South Bend Lathes
Landis Threaders	Dick's Balata Belting
Graton & Knight Leather Belting	Norton Grinding Wheels
Yale Chain Hoists	Fairbanks-Morse Generators
Gould's Pumps	Fairbanks-Morse Pumps

And Fairbanks-Morse products are themselves second to none in quality—each one has built up a reputation for reliability.

The Canadian Fairbanks-Morse catalog is a dependable buying guide because it lists machines and machine supplies—for every requirement—made by the world's foremost manufacturers.

Pumping By Electricity

INCLUDED in the equipment of the Hamilton, Ont., pumping plant is the electric motor driven pump shown herewith. This pump delivers 8,350 gal. per min. against 300 ft. head when running at 750 r.p.m., and is driven by a synchronous induction motor.

The low starting torque, high efficiency and power-limiting characteristic of the De Laval centrifugal pump are highly favorable to electric motor drive. In the present case, the motor starts as an induction motor, and then by switching on a direct current exciter, to be seen on the end of the shaft, the motor synchronizes itself and continues to run as a synchronous machine. In this way the unit is not only self starting, but may also be used to overcome the effects of induction motors on the same line and improve the power factor.

Both parts of the pumping unit are simple in construction and require practically no attention. De Laval centrifugal pumps are made to limit gages on an interchangeable basis. The labyrinth type of wearing ring insures the maintenance of high efficiency over long periods. The wearing ring and impeller are of bronze, as also are the shaft protecting sleeves. Any of these parts can be inserted by ordinary workmen.

State requirements, and our Engineering Department will supply estimates and guarantees.

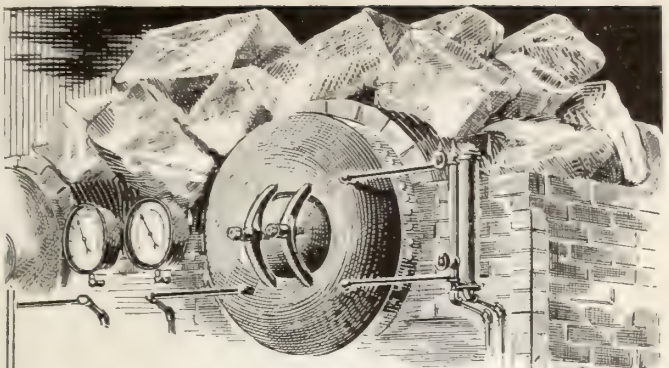
2)



Keep Your Boiler Packed with Ice

By packing ice around your boiler you will reduce the temperature. This makes it more difficult to keep steam up. More coal will be required. Your fuel bills will be higher.

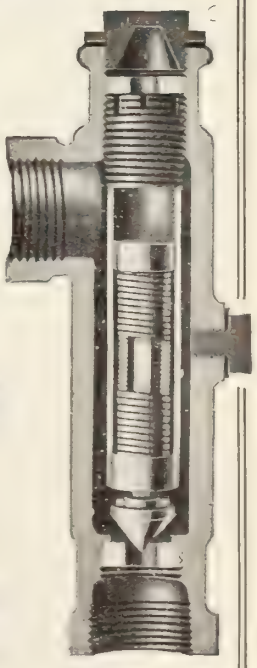
Ridiculous? Of course it is! But not any more ridiculous than the practice of trapping steam lines a hundred feet or more from the point where steam is used. Every foot of pipe that contains condensate is a foot of pipe that cools steam off and wastes coal! Get rid of the condensate where it forms, instead of at distant points, and cut down this waste! It requires more traps to do this, but the cost is comparatively light when your lines are fitted with the low-priced

STEAM TRAP SARCO

You can buy three Sarcos for the price of one bucket type trap, and by placing them where the condensate forms, you can draw it off instantly, instead of allowing it to drain back through enormous lengths of pipe, chilling the live steam in its progress.

Despite its small size, the Sarco is a little giant for performance. It drains the condensate off as rapidly as it forms, returning it instantly to the hot well without loss of heat units.

Many engineers have marvelled at the simple but scientific construction of the Sarco—the highly sensitive thermal element—the absence of complicated parts.



A 30 Days' Free Trial

will prove to you that the Steam Trap Sarco is a money saver. Quickly installed, does not require pit- heading or platform-building. Made in sizes ⅜ in. to 3 in., for any given presure up to 200 lbs.

Write today for Booklet No. J. 26 and full particulars about Free Trial Offer.

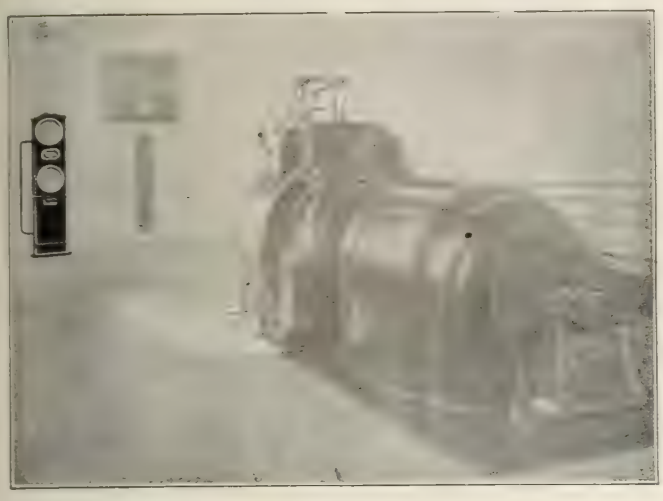
THE VENTURI METER GROWS WITH THE PLANT



Turbine Room, D. Goff & Son, Pawtucket, R. I.

When new boilers are added to the power plant old auxiliaries often have to be scrapped and new ones purchased. Not so with the Venturi Meters.

The measuring capacity of a Venturi is easily changed, at slight expense, by substituting a new throat section in the Meter Tube and new dials in the Register-Indicator-Recorder. Some Venturi Meters have been altered several times during their long term of service without impairing their accuracy to the slightest extent.

The Venturi Meter is used to measure boiler feed water, steam, condensation from heating systems, circulating water to condensers, etc., in the modern power plant. It is accurate, durable and positive; behind it is an enviable record of 30 years and thousands of successful installations.

PLIBRICO JOINTLESS

FURNACE LINING

PLIBRICO is a plastic refractory. When molded into jointless baffles, side walls, and arches, and properly baked and vitrified, it forms boiler settings that resist heat up to 3,100° F., that are air and gas tight, and that outlast laid-up fire brick many times.

When the first container of PLIBRICO is rolled into a plant, profits increase, for PLIBRICO means a saving of more than 10% on fuel bills; it is a time saver and a labor saver, and it is an insurance against loss from shutdowns for boiler setting repairs.

Get acquainted with PLIBRICO. Our book L-63 on "Modern Furnace Building," gives full information. Yours for the asking.

PLIBRICO is delivered only in steel containers of distinctive appearance, as shown below.

DISTRIBUTORS: Beveridge Supply Co., Ltd., Montreal, Que.; Shell Bar Boico Supply Co., Ltd., Toronto, Ont.; Evans Coleman & Evans, Vancouver, B. C.; Winnipeg Supply & Fuel Co., Winnipeg, Man.; Gorman's Ltd., Calgary, Alta.

Typical Installation of ELESCO SUPERHEATERS.

Section of **forged return bend** used in ELESCO SUPERHEATERS

ELESCO SUPERHEATERS

The Importance of Design—

A superheater requires as much study from an engineering standpoint as a boiler. Located in a high temperature zone, it must be insured against overheating. As steam must carry away this heat, great care is necessary to determine the correct amount of steam which should flow through the superheater.

In the ELESCO Superheater, high steam velocity is maintained, automatically keeping the inside of the units clean and protecting the heating surface.

The ELESCO Return Bend

Insures a leak proof construction

This return bend is **forged mechanically** on the ends of the units themselves, out of the metal of the unit pipes, without the use of screwed joints and without electrical or acetylene welding. The number of joints to be maintained steam tight is greatly reduced.

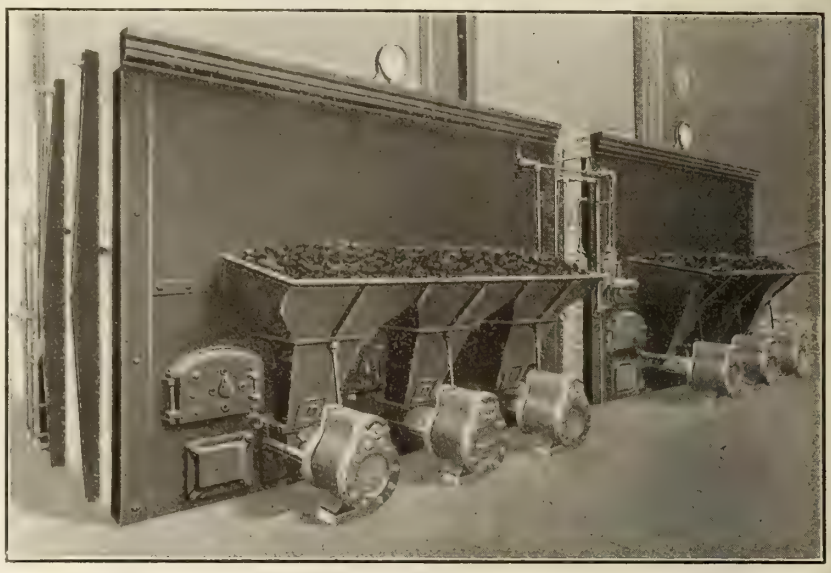
MACLEAN STOKERS

Will Save Coal From The Very First Day!

Wherever the MACLEAN STOKER has been installed the saving in both fuel and labor costs has been sufficient, in a very short time, to pay for the cost of installation.

The MACLEAN STOKER correctly proportions the coal feed and air supply to meet varying demands upon the boilers. These quantities are automatically controlled through the medium of the boiler steam pressure itself. It assures complete combustion and no matter what grade of soft coal is used there is NO SMOKE.



We will gladly give you an estimate of the saving to be made in your plant.

LUNKENHEIMER
Oil and Grease Cups
for Engine and Transmission Bearings

"America's Best since 1862"

The highly efficient results which Lunkenheimer Oil and Grease Cups give is but the reflection of close attention to details of design, the use of highest grade materials, accurate machining and the rigid test and inspection which they undergo.

These principles of construction have proved their real worth in service, and that first cost of Lunkenheimer Oil and Grease Cups is an inconsiderable factor as compared with the resultant economy in consumption of lubricant and insured life of equipment.

Modern engineering practice demands a specially designed cup for every purpose and this demand is successfully met by the variety of types and sizes of cups in the Lunkenheimer line.

Our descriptive booklets Nos. 523-DC and 524-DC will prove interesting to users. Shall we send you copies.

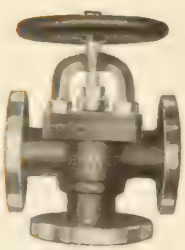
Beaver Valves

Globe Valve



Cross Valve

Check Valve
(Horizontal)

High Pressure Valves

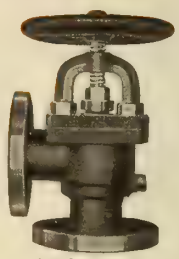
THE increasing use of high pressure steam has created a demand for something better than the ordinary Globe or Angle Valve. Even a heavier valve is not effective, it being a matter of change in design that is required.

"Beaver" Valves were specially constructed to meet this demand and from the very first have been highly satisfactory. They are made in a high-grade bronze in sizes 1-inch to 3-inch, and in iron or semi-steel body with bronze mountings, in sizes 2-inch to 12-inch.

Particular attention is directed to our improved joint between the body and the yoke, the machined faces of the double spigot preventing any possibility of the gasket blowing out. Particularly liberal allowance has been made in the construction of "Beaver" Valves in the areas through the body and seat. There is no cramping anywhere and although the areas are in excess of the nominal diameters of the connecting pipes (permitting a free flow of steam or water) the valves occupy a minimum of space.

"Beaver" Valves are designed for a working steam pressure of 250 lbs. per square inch and are subjected to a hydraulic test of 500 lbs. per square inch before leaving our factory. All parts can be renewed should they become worn or broken.

NOTE—Morrison "Beaver" Valve is the original of this type—all others are imitations. Look for the name "BEAVER."



Angle Valve

PENBERTHY

COMPODISK

Strong Where Others Are Weak

The one outstanding improvement in our valves over other makes is illustrated here.

It consists of THE OUTSIDE BONNET CONSTRUCTION. The bonnet **does not** screw **into** the body of the valve, it fastens to it by **outside** threads on the body; consequently, these threads never come in contact with the corrosive action of steam and water. They are **away** from it. The result is, the Valve bonnet and body can always be taken apart without strain or injury. This construction also prevents spreading of bonnet end of body when screwing down the bonnet tight; it makes them SAFE, SURE and STRONG.

Fig. 106
Jenkins Brass Globe Valve
(Standard Pattern)

Jenkins Designs Provide For Correct Valve Proportion

There are many types and sizes of Jenkins Valves, in Brass, Iron and Cast Steel.

Each valve is designed with mathematical accuracy assuring correct proportion, providing a stronger valve which will furnish maximum service even under the most severe working conditions.

Jenkins Valves for standard, medium or extra heavy pressures are sold through supply houses everywhere and are known by the Jenkins signature beneath a Diamond Mark cast on the body.

Look for this mark of the genuine when buying.

Files Hand Stokers Getting Results

PANTHER RUBBER COMPANY, LIMITED

GENERAL OFFICES AND FACTORIES
SHERBROOKE, QUE.

SHERBROOKE, CANADA September 23, 1921.

The Waterous Engine Works Co. Ltd.,
Brantford, Ont.

Gentlemen:

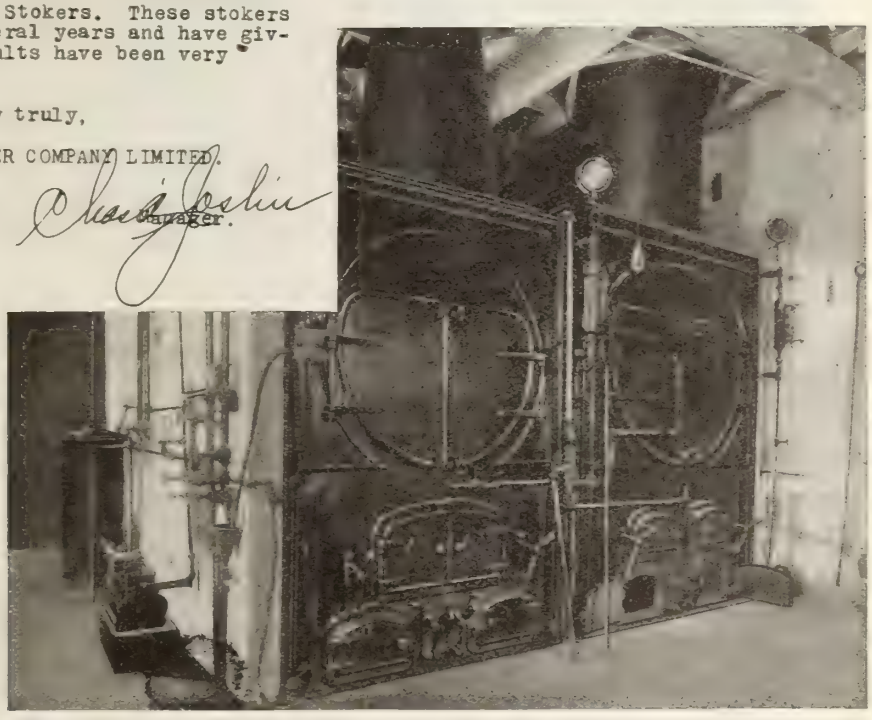
In reply to your letter of the 8th instant we have in our plant the Files Stokers. These stokers have been in operation for several years and have given excellent service. The results have been very satisfactory.

Yours very truly,

PANTHER RUBBER COMPANY LIMITED.

Manager.

CAJ/RMK



It is the uniform excellent service and general satisfaction that have caused progressive men to select **Files Stokers.** These are typical of the more complete data we have compiled:

One installation (3,600 H.P.) saved enough coal to pay for their stoker investment in five months.

A Files installation operated for five months continuously at an average rating of 223%—doubling their steam output.

Files stokers increased efficiency of one plant sufficiently high to warrant discontinuance of two out of eight boilers.

Here is a ready explanation of these achievements:—

1. **Complete volatilization of green coal, causing intensified combustion and smoke dissemination.**
2. **Correct distribution and proper proportion of air according to load carried.**
3. **Fuel bed continuously kept clean, uniform and rich.**

Given the opportunity we will be glad to present these facts for your complete satisfaction.

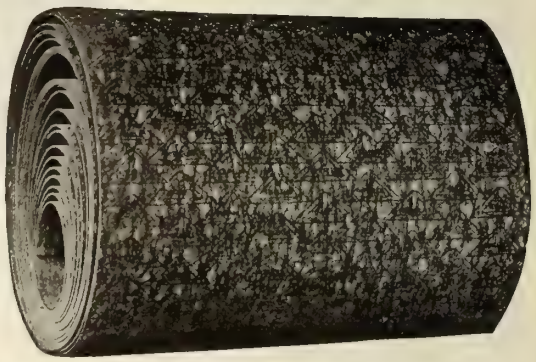
For Tight Joints



Durabla compressed asbestos fibre sheet packing makes tight joints on steam, water, air, oil, ammonia and acids at all temperatures and pressures. Joints can be broken without injury to gaskets. It will not burn out, blow out, pulp at the joints; requires no following up and is not affected by vibration or condensation. Durabla Packing meets all conditions of shipping and storage.

"P.M.S" BELTING

Built-up Plies of Cotton Duck Woven to our own specifications and firmly united by our Rubber Friction.

We have given special study to this branch of our business with the result that we supply "P.M.S" Belting in fullest confidence that it will meet successfully even the severest tests

For Effective Service in the Transmission Field

Our research has evolved methods that secure maximum adhesion, strength of fibre and age-resisting ability. Careful vulcanization to assure correct, uniform pressure, elimination of surplus elasticity and exactly the right temperature to properly cure the belt without burning the stock is an essential scrupulously maintained.

Our belting experts will be glad to recommend a solution of your problems in belting for all transmissions, conveying of hot or cold materials, bucket elevators, or practically any kind of belt service.

An inquiry involves no obligation.

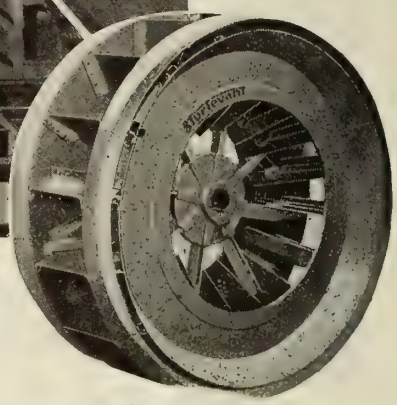
Installation in a Municipal Lighting Plant.



Rotating Member of the Cindervane.

The Cindervane Has Proved Itself

Actual tests showed that four requirements were necessary for catching cinders before they went up the stack to be distributed over the neighborhood. These were

High efficiency in cinder elimination. Reasonable first cost.
Slight reduction in Temperature. Low Power Consumption.

Actual practice shows that the Sturtevant Cindervane possesses all these necessary requirements to a considerable degree. In addition, a highly efficient induced draft is afforded.

It is the only unit made that serves this double purpose. The Cindervane eliminates cinders as satisfactorily as it gives an induced draft.

Every power plant is interested in abating the cinder nuisance. Before discussing your proposition with our engineers we would like you to see a Cindervane under actual working conditions.

Send us your name so that we can forward the address of the installation nearest you.

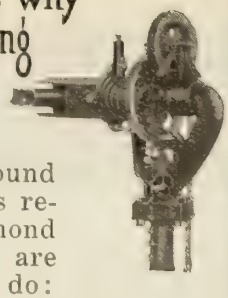
There are reasons why Central Stations are buying Diamond Valv-in-Head Soot Blowers



The Central Stations have found that the operating economies resulting from the use of Diamond Valv-in-Head soot blowers are tremendous, including as they do:

1 LABOR—a saving of approximately 50 per cent.
2 STEAM—a saving of 40 to 50 per cent. or more.
3. PIPE VALVES and FITTINGS—a saving of 50 to 66 per cent. in cost of pipe, valves and fittings.
4 MAINTENANCE—a reduction in annual charges of 25 to 50 per cent. or more.
5 EFFICIENCY—greater cleanliness of boiler assured.

Among recent Central Station purchasers of 100 units or more may be mentioned:

Commonwealth Edison Company

Detroit Edison Company

Penn. Power and Light Company

Within the last few months orders have been received to equip over 125,000 h.p. of Central Station boilers. Diamond Valv-in-Head soot blowers pay big dividends on the investment in them.

If the central stations find that Diamond Valv-in-Head soot blowers save fuel, labor and steam, it is obvious that they can be installed profitably on every high pressure water tube boiler.

Diamond

VALV-IN-HEAD SOOT BLOWERS

A fact that is commanding greater respect every day—

"THE problem of efficient combustion is primarily one of always regulating both fuel and air supply simultaneously, so that the ratio of air to fuel will always be uniform. After the correct ratio is established, the fuel may burn fast or slow according to the demands for steam, but by modern means of control can be made always to combine in whatever ratio is found to represent best economy."

THIS constantly repeated fact is becoming a law—an axiom of correct combustion. And it is significant that the value of this principle was recognized by the Under-Feed Stoker Company of Canada years ago; automatic control of fuel and air was applied for the first time in the Jones Stoker. An automatic regulating valve is installed on the steam line and this speeds the fan engine and Cole Automatic Valves when the steam pressure tends to drop, likewise slowing them when the pressure starts to fall off. The Cole Automatics increase the speed of the coal ram so that the ideal ratio of fuel is always maintained. An even steam pressure and complete combustion is thus maintained. Eight different points of adjustment are provided, so that the automatic control can be easily set at the point to give best combustion with the particular coal being burned.

As significant as the automatic control of fuel and air are many other vital features. The story of these is told in the Jones "A-C" catalog. Ask for it.

Asphalt mastic finished Nonpareil Corkboard Insulation on one of the rooms of the Avondale Ice Company, Cincinnati, Ohio.

Getting Results with Insulation

Getting results with cold storage insulation depends as much on proper planning as on the material itself. Unless the insulating material is specifically adapted in thickness and method of erection to the conditions in your plant, it cannot be economical and may not be permanent.

The predominating superiority of Nonpareil Corkboard Insulation is not due entirely to the efficiency and durability of the *Insulating Material* —Nonpareil Corkboard. Equally important is the technical service which designs your insulation in thickness and structural detail to suit your requirements and to give you the maximum value in operating economy and investment return.

Instead of worrying with the technical details of materials, thickness and construction, why not enlist the help of those whose business it is to know these things? This Company offers you, without charge or obligation, the assistance of trained men to analyze your plant conditions and to work out the methods of insulation that will give you the most economical and permanent results.

"Ask Armstrong" is the advice you will get from operators and engineers who have learned to depend for results on Nonpareil Corkboard Insulation.

Write for the 152-page book, "Nonpareil Corkboard Insulation." It contains essential facts about insulating low temperature rooms which you will find both helpful and interesting. No charge.

NONPAREIL CORKBOARD INSULATION
For All Cold Storage Rooms

More Than Ten Years' Service

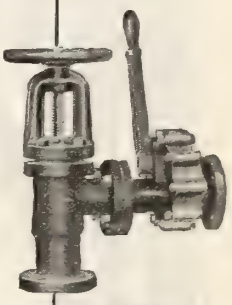
Not One Cent for Repairs

The two Yarway Seatless Blow-Off Valves shown below are in the plant of the Riverside Highland Water Co., Colton, Cal.

These valves have been in continuous service since their installation in February, 1912. One has never been repacked; the other was repacked once.

The packing used was furnished with the original order, so these two valves have not cost one cent for repairs in ten years of service. Recently, they were reported both absolutely tight.

Records like this indicate one reason why so many careful, economical operators prefer the Yarway Seatless Blow-Off Valve. The whole story is told in Booklet B-410—awaiting your request.



If you require two valves on the blow-off line, remember this: the Yarway Seatless and Yarway Double Tightening Valves in tandem give blow-off security and satisfaction.

Genuine British Oak Tanned Belting

Put it to this test---

If you have a particularly difficult problem in transmission—one for which ordinary belting has proved unsatisfactory—put a D. K. McLaren British Oak Tanned Belt to work and you will appreciate, as others have done, its wonderful toughness and pliability. This extraordinary gripping power (preventing slippage and other trouble) is the direct result of the long-time process of British Oak Tanning to which it is subjected. It is the reason back of our claim that D. K. McLaren Belting reduces transmission costs to a minimum.

Taking the "stuff" out of stuffing boxes

Making packing tight by screwing up the gland creates friction that destroys the packing and wastes power.

That's why Sea Rings are different — they require only sufficient gland pressure to prevent their moving in the stuffing box.

The lips of Sea Rings are adjusted by the action of the pressure they pack against, tightening as the pressure increases and loosening as the pressure drops. The pliant lips of Sea Rings bear on the rod with the minimum pressure necessary to prevent leakage.

Packing life is prolonged by removing the cause of its destruction. As a result, Sea Rings will outlast ordinary packings many times over.

That is not all. Reduced friction saves power — it actually cuts your power cost. Sea Rings are saving thousands of dollars yearly in many plants.

The Tidewater Paper Company made one of the many tests that have proven the actual saving effected by Sea Rings. The Sea Ring Booklet gives the results. Send for it.

"Shooting" the Man from Glengarry

THE Ottawa Valley has witnessed scenes during the past few weeks which have never before greeted the eyes of the dwellers within its limits. Realism—the sinewy log drivers, cleverly and daringly facing the camera; beautiful women rescued from the river's icy waters—terrific raft fights—log jams, where lean river men stepped from the playing of a part into real life—lumbermen armed with peevies and pike-poles, striving to break the menace of locked logs—all these are features of the most stupendous Canadian story yet filmed within the borders of this Dominion.

Ernest W. Shipman has been producing "The Man From Glengarry," Ralph Connor's masterpiece—and filming it with all the fidelity and accuracy which modern ingenuity can command. Those who have been privileged to witness these scenes have watched in action pretty, vivacious Mayme St. Clair, Bully Lenoir and Big MacDonald, reproducing the action contained between the covers of Ralph Connor's dramatic work.

Archie McKishnie has recently spent several days with Mr. Shipman's company and has told the story, in

BAILEY BOILER PANEL

Shows Every Detail of Boiler Operation

With the various details of the many operations clearly indicated; with draft, stoker and other controls at hand; the operator can operate the boilers as easily and intelligently as the switchboard man handles the electrical load in a central station. With the Bailey Boiler Panel, a combination of the Bailey Multi-Pointer Gage and Bailey Boiler Meter, the operator has everything right before him to obtain the desired capacity and best efficiency at all times.

The Bailey Boiler Meter is a reliable guide for the fireman in that it shows him exactly what the conditions are at every instant—information that permits the correction of bad conditions as soon as they occur. The Meter records: (1) the rate of Steam Flow; (2) the rate of Air Flow; (3) the average Temperature of all the Gases leaving the Boiler.

The Bailey Multi-Pointer Gage is made with any number of pointers from one to twelve. Scales and graduations distinctly marked. It has inside illumination. The six-pointer gage here shown includes Steam Pressure, Feed Water Pressure, Rate of Flow of Feed Water, Wind Box Pressure, Fire Box Draft and Draft at Damper.

The Thirty-Third C. A. S. E. Convention

Some Changes Looking to the Advancement of the Association Were Made in the Constitution—Interesting Lecture on Flow Meters—Picnic, Dancing and Social Activities Provide the Lighter Side

ANOTHER convention of the Canadian Association of Stationary Engineers has gone into the pages of history, and the eyes of the members are now turned toward the future and other conventions.

It is unfortunately true that there was not as large an attendance at this year's event as there has been at some of the others, at least so it seemed to those who had goods on exhibition there, but perhaps one reason was that strangers seemed to have considerable difficulty in finding the hall. To the inhabitants of the town it was a familiar spot, but to a visitor it presented difficulties. Owing to the fact that there was a sign outside exhibiting the initials Y. W. C. A., some of the more bashful visitors hesitated about entering.

The Official Opening

The real opening of the convention was on the Tuesday morning, although on the previous evening the Grand Lodge held an executive meeting, this being of course in camera. During the evening while this was going on the exhibitors were busy getting their stalls in order for the following day, and some of them found then that they could not, unfortunately, get their heavier exhibits into place. However, they made the best of it, and used unlimited quantities of crepe paper and bunting to hide the deficiencies. At 10 o'clock on Tuesday morning the various delegates, members of the Grand Lodge, exhibitors and visitors, assembled in the hall of the Dominion Tire Systems to officially declare the meeting open. There were present in addition to the officers of the C. A. S. E. the Mayor of Kitchener, Mr. Charles Greb, and Mr. Nicholas Asmussen, the M. P. P.

The president of the local Lodge, Mr. Pflug, introduced the mayor in a brief speech, in which he spoke of the advantages of the town as a manufacturing and residential city. The Mayor, on rising, welcomed the delegates, exhibitors, and visitors to the city, and passed some complimentary remarks on the exhibit in the adjoining room. He wished everybody present to enjoy the advantages of the city to the full during their stay.

Mr. Asmussen, following the Mayor, regretted the fact that they could not display all the hospitality that they had on former occasions of the convention being held in Kitchener. He won the sympathy of the majority of those present, by stating that he hoped that in the near future, the legislature would pass saner legislation, which did not interfere so much with the tastes of the general public, and would give them back the freedom which had been such a strong point with their forefathers. From the cheers with which these sentiments were received, there were not many present who were in favor of prohibition.

President Harper of the Grand Lodge explained in a few words just what the objects of the Association really were. He stressed the fact that its great reason for existence was the facilities it held out for engineers to improve thier knowledge of their profession, and become more valuable men to both themselves and the community in general.

Exhibitors, Delegates, Ladies and Visitors in Victoria Ball Park.

While it was a fraternal society in a way, this was overshadowed by its educational features.

Mr. J. Thompson of the Dearborn Chemical Co., spoke a few words in commendation of the city, and pointed out to the mayor that he had neglected to offer the convention the freedom of the city. The Mayor promptly rose and rectified this omission.

Mr. Soucy, a delegate from Toronto, also spoke as one who knew Kitchener from the fact of having lived in it for a number of years, and had many words of praise to give.

Mr. T. H. Fenner, editor of Power House, also addressed the meeting, as did Mr. Gordon Keith, editor of "Canadian Manufacturer."

Mr. Harry Wright, delegate from Montreal, and the Vice President of the Association, (now the President), departed from the subject in hand long enough to give the assemblage a recipe for making Californian bee wine. It appears this Californian bee is a species of plant, which can be induced to yield a tasteful liquor if properly treated. It developed that in Mr. Wright's capable hands it accumulated quite a sting, and this not being enough for the jaded throats of the Montrealers, he added a little whiskey and port wine. The meeting listened with great approval, and Mr. Wright thereon developed another theory on the capabilities of cocoanuts if mixed with the right constituents.

Leaving this fascinating subject, he came back to the purposes and advantages of the C. A. S. E., and especially pointed out the advantage it might be to the man in the smaller town, and the smaller plant, who did not get the opportunity of seeing for himself the more modern developments in power plant work. These men, through intercourse with the other branches of the society, and by the fact that there were lectures delivered from time to time on these subjects, could at least become familiar in a general way with things they would otherwise never meet. He also pointed out how the technical papers, such as the Power House, could help them, and alluded to the support this paper had given to the organization.

A few words from Mr. L. J. Ellis, the Grand Secretary of the Association, concluded the proceedings.

Adjournment was then made to the Exhibition Hall where the following firms had their goods on display:—

Jas. Morrison Brass Manufacturing Co., Toronto, valves, injectors, gauges.

Babcock and Wilcox Co., Montreal, boilers and accessories.

Black Donald Graphite Co., Calabogie, graphite products.

Darling Bros. Montreal, heating appliances, valve re-seating tools, etc.

C. B. Turner and Co., Toronto, boiler scale separator, and tube ferrules.

Empire Brass Manufacturing Co., London, valves, etc.

Thompson, Gordon Co., Hamilton, packing, etc.

Waterous Engine Works, Brantford, exhibiting Files stokers.

Goldie and McCulloch, Galt, engines, boilers, Rees Roturbo pumps.

Quaker City Rubber Co., Philadelphia, packings.

Lunkenheimer Co., Cincinnati, valves.

Crane, Ltd., Montreal and Toronto, valves, equipping and fittings.

Garlock Packing Co., Hamilton, packings.

Dearborn Chemical Co., Toronto, boiler scale treatments.

Jenkins Bros., Montreal, valves.

Atlas Machine and Engineering Works Toronto, Attwood Pump.

Power House, Toronto.

Canadian Manufacturer, Toronto.

A drive had been arranged for the ladies of the party for the afternoon but unfortunately the weatherman turned peevish, and this had to be abandoned for the time being.

While the Grand Lodge was in session Tuesday evening, a lecture had been arranged for the entertainment and instruction of the visiting delegates and members of the local lodges, who were not required at the Grand Lodge meeting. This lecture was delivered by Mr. Mess, of the Dominion Flow Meter Co., and the subject was "Flow Meters." The lecture was illustrated by a large number of slides, and it was handled by Mr. Mess in a way that made the construction and operation of these instruments quite plain to all those present.

After the lecture, Mr. T. H. Fenner of the "Power House," by request of the Grand Lodge, gave a short lecture on the aims and objects of the C. A. S. E. to the audience, many of whom were non-members of the Association.

Wednesday's Events

The morning was devoted by the delegates to a session of the Grand Lodge, and the exhibition hall remained open during the morning for those who cared to come. It is rather to be regretted that very few took advantage of this opportunity, for there is no doubt that it would have been an education to a number of them had they done so. It is rather discouraging to those exhibiting, who are put to a considerable amount of expense in preparing and shipping their goods, when so little interest is displayed by those attending the convention. It would be an excellet opportunity for the engineers in the convention town to get their managers, superintendents, or the owners of the firms themselves to visit this exhibition, and get an idea of the various appliances that are manufactured for power plant uses.

The big event as usual was the picnic, at which the delegates and their wives, and friends were the guests of the Exhibitors' Association. The sports events were carried off in the Victoria Park, after the crowd had first been photographed by Mr. Denton, the official photographer, for the occasion. This photograph is reproduced here. The winners of the various events were as follows:

One Hundred Yard Dash:—Geo. Wilkinson, first; J. Thompson, second.

Balloon Race— Doris Lodge, first; Vera Karn, second.

One Foot Hop Race—J. Hughes, first; J. Thompson, second.

Ladies' Candle Race—Mrs. Anneveld, first; Mrs. Kirsche, second.

Backward Running Race—G. F. Galloway, first; W. L. Kohl, second.

Ladies' Clothes Pin Race—Dorothy Ott, first; Mrs. Goften, second.

Men's Smoking Race—Ed. Reiber, first, Wm. Lodge, second.

Potato Race—Bertha Kirsche, first; Mrs. Gofton, second.

Wheelbarrow Race—B. Myer and S. A. Jennings.

Little Boys' Race— Jim Hetherington, first; Ed. Luft, second.

Little Girls' Race—B. Gastemier, first; Mary Taggart, second.

In the soft ball game between the engineers and exhibitors, always a well contested event, the engineers were victorious by 10 runs to 3. The umpire Mr. E. A. Wilkinson, discharged his unpleasant duties with a commendable firmness, though we say nothing about his ability in any other way.

After the ball game everybody departed to their various resting places to prepare for the concert and dance which was to feature the evening. This event was pulled off with the usual eclat, and the dance especially was much enjoyed by all present. Owing to the kindness of Mrs. Ott a good many of the visitors had been able to limber up at a little informal dance held at her house the previous evening.

The prizes for the Educational Contest among the various lodges of the C. A. S. E. resulted in Toronto securing the first prize, with Ottawa, second, and Kitchener third. Kitchener also won the prize for the lodge obtaining the greatest membership during the year.

Get Away Day

Thursday was the winding up day of the Convention. The Grand Lodge officers met and elected the officers for the ensuing year, and after the election Mr. Brown, Chairman of the Board of Stationary Engineers, Mr. Medcalfe, Chief Boiler Inspector of the Province of Ontario, and Mr. T. H. Fenner, editor of "Power House" addressed the Grand Lodge on the subject of the boiler and stationary engineers' acts, and their administration.

Mr. Brown made it clear to the officers of the Grand Lodge that there was nothing to fear from the special certificates which have been discussed at some length in this paper. Mr. Medcalfe spoke on the administration of the boiler inspection laws, and pointed out where certain weaknesses lay in the acts appertaining to the inspection of boilers.

The following officers were appointed for the ensuing year, and were installed the same afternoon:

Delegates With Their Ladies.

MEMBERS OF GRAND LODGE.
Top Row: R. E. Arnup, Woodstock, Conductor. F. Harper, Kingston, P.P., Galloway, London, V.P.
Bottom Row:—L. J. Ellis, Hamilton, Secretary. H. Wright, Montreal, President. J. J. Sullivan, Ottawa, Treasurer. T. Turner, Toronto, Doorkeeper.

H. Wright, Montreal, President.
F. H rper, Kingston, Past President.
J. Galloway, London, Vice-President.
L. J. Ellis, Hamilton, Recording Secretary.
R. E. Arnup, Woodstock, Conductor.
T. Turner, Toronto, Doorkeeper.

Probably the most important work performed at the convention as far as the Association is concerned was the amendment of the constitution, by which the ritual formerly in use h s been practically abolished. We shall be able to give further particulars in a future issue in this regard.

The exhibitors association also held their annual meeting on Thursday morning, the 28th June, the general routine business being gone through. There was, however, one resolution of extreme importance which probably has considerable significance to the C. A. S. E. and future convention success. It is as follows:—

"It is hereby resolved that before the Exhibitors Association meet at the point chosen by the Grand Lodge of the C. A. S. E. that the President of the Exhibitors Association get in touch with the local lodge, and find out what facilities they have provided for holding an exhibition, and, if they have not proper facilities, the executive of the Exhibitors Association is to select their own place of meeting."

The following gentlemen were elected to hold office for the ensuing year:

President, J. Thompson, Toronto.
1st V. P., H. Fletcher; Toronto.
2nd V. P. E. Hetherington; Galt.
Secretary, G. Keith; Toronto.
Ass. Sec., Geo. Wilkinson.
Treasurer, R. M. Archibald; Toronto.
Chairman of Committees:—
Exhibition, C. B. Turner.
Entertainment, E. Hetherington.
Reception, H. H. Gee.

The place of next year's convention will be Toronto, and it will be held as usual in the last week in June.

£10,000 FOR RESEARCH

The name of Parsons is known all the world over in connection with the invention of the steam turbine which has made possible the cheap production of electricity in large quantities and the development of high speeds by large ships. In addition to inventing the turbine Sir Charles Parsons has rendered great service to the progress of science and the latest sign of his interest in the field is the gift of ten thousand pounds to the British Association for the Advancement of Science. Since it was founded in 1831, the Association has made grants of over eighty thousand pounds towards scientific research. Sir Charles' latest gift will enable the Association to maintain its important work of scientific investigation. In connection with the speed of ships it is interesting to note that the fastest ship afloat is a British vessel, the "Mauretania," and during a recent voyage from the United States to Great Britain she maintained an average speed of 25.14 knots, and at one stage she attained 27.5 knots. This was the fastest trans-atlantic cruise made since the war, and it is faster than the same vessel had ever attained.

NEW PUBLICATIONS

A line of velocity stage turbines especially designed for high pressure and high temperature steam is described in a 28-page catalog issued by the De Laval Steam Turbine Co., of Trenton, N. J. The cast steel steam chest is located in the casing cover in order to avoid the conduction of heat to the bearings. In addition to the speed governor and governor valve, there is an independent valve controlled by an automatic overspeed trip. The turbines are built in sizes up to 1,200 h.p., and are designed to be directly coupled to high speed centrifugal pumps and blowers, small AC and DC generators, and by means of double helical speed reducing gears, to large pumps and blowers, medium size generators, belt pulleys, rope sheaves and slow and moderate speed machinery.

The Conveyors Corporation of America, 326 West Madison Street, Chicago, Ill., have just issued a new booklet describing their American Cast Iron Storage Tank, which is designed for holding loose, bulky, dry materials for storage or transfer. The tank is sectional and may be secured in a number of sizes.

The booklet is illustrated with engravings showing the tanks in use at a number of well known plants. Diagrams give details of construction and a comprehensive table of weights and measures is included.

Copies of the booklet may be secured by addressing the Conveyors Corporation at 326 West Madison Street, Chicago, or on application to their district representatives.

The Bureau of Labor, Province of Manitoba, have issued a book containing the Inter-Provincial Boiler Regulations. No doubt these books will be available to Ontario manufacturers and boiler users very shortly, but we understand that at the moment they are not all off the press. The book contains complete information on preparation of designs, tests, etc. to satisfy the regulations of the provinces agreeing to the regulations, which include British Columbia, Saskatchewan, Manitoba, Alberta, Ontario, Quebec and Nova Scotia. The regulations are intended to serve the double purpose of ensuring safe boilers, and at the same time standardising design and construction, with the advantages accruing to both manufacturers and users from such standardisation.

Some More Discussion on Burning Wood Fuel

The Search for the Most Efficient Method of Burning a Mixture of Wood and Coal is Continued and Some Valuable Thoughts Are Brought to Light in the Process

By "JOHNNY SHOVEL"

AS WE said before, everybody had a theory as to how the conditions at the mill could be improved and the firemen were not so exclusive that they stood out of it. Quite the opposite, and bless them, they didn't stop at the furnaces, but joined forces in condemning the boilers as well.

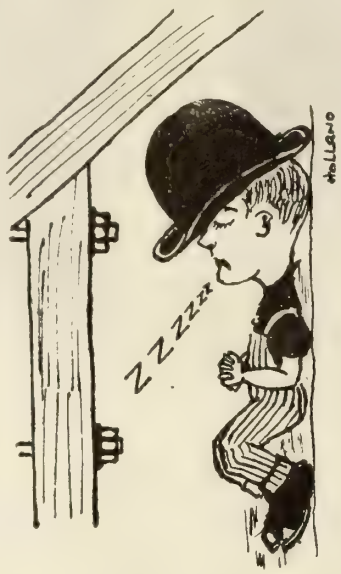
With our personal education they had a great deal to do and while they looked down on us owing to our lack of years, and depreciated our efforts in rough language, they gradually came to interest themselves in our search for knowledge. Probably they came to believe that we were filled with "insatiable curiosity" and like Kipling's "elephant child," it would lead us to something better. Without the knowledge of the "powers" they gave us a hand to find out how to suit the fire to the quantity of stuff coming over.

He was a curler.

First we tried mixing the shavings with coal before we put them into the furnace, because it is not very easy to throw a shovelful of shavings to the back of a 7-ft. furnace. They have to be mixed with saw-dust or coal or they will not make the distance, no matter how much force is used.

After a time we discovered that every boiler was an individual as far as the dampers were concerned, a TRUTH which applies to ANY boiler wherever it may be and whatever the furnace or fuel. In this case we wanted to get a strong draft but not so fierce that it would carry a lot of the fuel over into the boiler. With the help of a quantity of dry shavings we were able to establish this limit for each unit.

We had only the steam pressure gauges and the quantities of coal in the cars to estimate with and naturally there was a lot of argument, but it eventually became the rule, when we were getting plenty of stuff from the mill, to fire heavily with the stuff and then bed the coal on top.



No man who works in constant danger of hitting his head should be without one. It gives such a wonderful feeling of security if your favorite place to sneak a nap happens to be restricted.

This is the second of a series of articles on the practical operation of boilers by a man well qualified to speak on the subject. He is writing them in plain language, and avoiding technicalities. There will be a fund of information found in these articles for all classes of engineers.

The cap kept the dust out pretty well, and by ignoring the injured looks of our landlady when she would discourse with us on the washing of dirty pillow cases, we managed to get away with only one really truly head wash each week.

When we had to burn half and half, we found it a good plan to make a thick coal fire at the bridgewall, tapering it off to the grate about four feet out. We could keep this fire in good shape by feeding coal to it over top of the stuff, and we could fire any kind of stuff in front. The scheme had the added advantage that if the blower was not sending us much, it was easy to bring the coal fire along to the required size, even to cover the grates. Reversely, it was a simple matter, if the stuff began to pile up on us, to shove the coal fire to the rear of the grate and fire with it again.

The saving in coal was something and the improvement from the firemen's point of view quite appreciable. They were more comfortable in mind, but still there was no necessity for any worker in that boiler room to be rocked to sleep.

We hear that the boys back from overseas have gone one better by wearing their 'tinlids' and they go about their business with a most complacent smile regardless.

Our master mechanic was a Scotsman, and a great curler. It was not to be expected that our efforts could escape him, but we were surprised and we understood that our energy had been properly appreciated, when he stopped one day to remark "Some day laddie, we'll make a guid stane man o' ye." The height of praise from the gentleman was that "it's no so bad," and to be considered as a possible member of the "Curling Club" was an honor almost overwhelming.

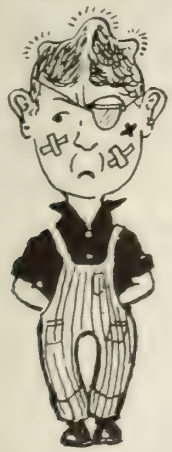
The biggest lumber company in our district had their largest mill about 15 miles from town. One day we were struck with the mighty fact that they certainly burned wood there if any place in the country, and the views of the man in charge would be interesting.

He Got An Order.

So, we made up to the boys of the "shunter" crew and finally got a free ride to the forks. We rode in the engine. My word, it was a wonderful trip. The time passed all too quickly while we picked up full cars here and there and placed "empties." We were firmly convinced that when we got back home we would apply to the railroad for a job and become a locomotive engineer.

That thought didn't stay very long. The size and class of the equipment at the saw mill surprised every other idea out of our heads. We were, almost, afraid to talk up to the men working there, we felt so humble in the midst of, to us, ponderous machines. The "chief" was good enough to take us in hand and explain all we could absorb about the equipment under his charge. He was one of those long, thin individuals who do not show their age, but his stories indicated that he had been a long time in the business.

"Yes", he said, "burning wood is getting to be more of an art these days. Most of the stick is marketable and they ship out everything that will make a match. There is nothing like the same amount of wastage, and since what



We started to work with the idea that a cap worn on an inside job would take all the hair off our head. We didn't wear one till we got good and tired of washing our hair and mending the bruises and cuts where our head met sundry obstruction.

is left is supposed to make the steam needed to keep everything going just the same, one has to use some judgment in burning it." After we had sketched our layout for him and told all we knew about conditions, he concluded, "that if he had to do the job, he would put in an 'Extension Furnace.' nil. You need plenty of combustion space, but there is not enough moisture in that stuff of yours to require a Dutch oven. Our stuff here is straight out of the mill pond and we have to have a lot of heated brickwork to radiate heat to it and drive the moisture out.

"Since you have H. R. T. boilers, you have to figure on getting your combustion straight along the shell. Space is space whether it lies horizontally or vertically, but the distance from the grates to the shell should be more than most people allow, say about 5 feet, so the stuff can pile up in a cone under the feed holes. Your Joe Leblanc, in his high set B. & W. boilers, has enough furnace volume to burn his stuff without extension furnaces. Rated by the quantity of moisture, he is at one end of the wood fuel burning game and you are about half way between him and me. If you had B. & W. boilers, set a bit higher than Joe's, you might burn

It didn't stop the bruises nor all the cuts. A light cap is poor protection against the end of a bolt that wishes to slay you. We still saw stars very often. One day we got a bang that made us see daylight, and immediately we promoted ourself to a hard hat.

your stuff without the extension furnace."

We had thought, from what our mill engineer told us, that all Dutch Oven furnaces had grates slanting to the boiler, but the grates at this sawmill were flat. Mr. Dobson said he had been in Newfoundland at one time, working for a British firm, and the grates in that mill were slanting. He thought it was British practice to arrange them that way and with the chutes leading into hoppers outside the furnace altogether, so the stuff would roll along down the grates without piling in heaps. The practice of having the grates flat was American, but the effect was really just about the same, for the slanting grate was represented by the cones under the feed holes.

They were "hogging" most of t' wood, that is, passing it through a machine which ground it to shreds. It traveled to the furnaces by conveyers,

passed down the chutes and piled up on the grates in cones about four feet high, each chute feeding something like 32 sq. ft. of grate. We got another surprise at seeing clinkers coming from one of his boilers. "How did they get it?" "Well, that boiler was the first on the conveyer and nearly all the earthy material, picked up by the logs while coming down from the woods to the mill, fell into that furnace and it made clinkers just as the same ingredients in coal would and did make. It is not wise to try and clean that fire. In fact, it is plain dangerous and we have had a good many firemen burned because they would take a chance and stick a hoe into a cone. The interior of the cone seems to contain steam or gas which explodes when the necessary air gets through it, and Mr. Fireman is caught by the rush of flame through the fire door. It doesn't always explode; they get away with it, only to find that pulling down the cone puts the fire out around the edges of it.

"Our load is reasonably steady, but we have things arranged so that we can take care of a demand for more steam. We have the feed holes on two furnaces set six inches nearer the boilers than the others, so the front of the grates

All He Had To Do.

has a longer bare space. When the demand for extra steam comes, we fire blocks and slabs in the front end of these furnaces and 'hump' them up above rating."

Of course, the fact that the firm was considering a change, got to the ears of every supply man in the district and we had a good many of them down to look over the proposition. Some of them made suggestions and some promised miracles. Most of them contributed to the general fund of information, so that the boss was able to base his report on a real knowledge of the conditions. The firm went thoroughly into it and one result was, that afterwards all the timber they brought from distant points came "dimensioned" so there was nothing much to come off it and nothing like the same amount of stuff coming over to burn. Guess they figured it was cheaper to have the sticks made to size than to pay freight on a lot of wood whose value as fuel didn't pay it by a long shot.

As for the actual question, it wa solved in a very different manner from what our wise ones expected. A salesman for underfeed stokers dropped in, made a bargain for his machines and got away before we had a chance to tap his store of knowledge or even get a few of the latest stories. The stokers arived promptly and we fitted a boiler each week till they were all in place.

Say, but we were proud of those things for the first while, but still it was a busy job, for the stuff from the mill and the coal had to be shovelled into the hoppers. What was the best way to burn it? Mix it all together? Fire coal and then shavings? Or fire all the coal by stoker and the shavings in the good old way, through the fire doors? After some experimenting, this last method proved to be the best for us. The next spring the boilers were raised and the chutes arranged so what stuff there was dropped straight into the furnace, then the firemens' energies were expended on the valve chains.

HOW MUCH POWER IS THAT BELT TRANSMITTING?

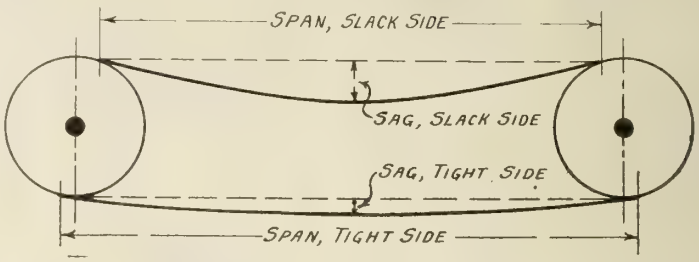
(A method that gives the answer without the use of complicated instruments.)

By W. F. Schaphorst

When a horizontal belt is in operation, and most important drive belts are horizontal or nearly so, it is a well known fact that no matter how great the load that is being transmitted there is a sag in the "tight" side of the belt as well as in the slack side. It is impossible to make the pull so great that the tight side will be perfectly horizontal, or a perfect straight line. There will always be a sag. The greater the load, the less the sag on the tight side and the more the sag on the slack side.

In view of the fact that this sag on both sides varies with the load being transmitted and in view of the further fact that the tension in a belt can be accurately computed when the sag and span are known, it becomes possible to compute the power being transmitted by any horizontal belt. To assist in these computations the writer has prepared a table which is reproduced herewith. It is a simple matter to measure the sag and the span with an ordinary yardstick. Four other measurements are necessary—the width and thickness of the belt; the outside diameter of one of the pulleys; and the revolutions per minute of that same pulley. These measurements may all be taken with the same yard stick and with an ordinary watch.

To determine the horsepower being transmitted by a given leather belt of any width and thickness, measure the span of the slack side as indicated on the sketch. This span is NOT the distance from center to center of the shaft but is the distance between the points where the belt leaves one pulley and touches the other. Then measure the sag. The sag is the greatest vertical distance between the belt and a straight line connecting the contact points as shown on the sketch. Next, measure the span and sag of the tight side again, observing the points of "making and breaking contact" as explained above. It makes no difference whether the belt is a "bottom pull" or "top pull" belt, this method will give the horse power transmitted in either case. Then, referring to the table, find the tension corresponding to the span and sag of the slack side, which we will call A. Then find the tension corresponding to the span and sag of the tight side, which we will call B. Subtract A from B. Then multiply by the width of the belt in inches. Then multiply by the thickness of the belt in inches. Then multiply by the outside diameter of one of the pulleys in inches. Then multiply by the revolutions per minute made by that same pulley. Then multiply by .000007933. The answer is the horse power being transmitted by the belt at the same time of measurement.



Finding the power a belt is transmitting

In case the sag is less than one inch, which may often be the case where pulleys are close together, this same table can be used by simply shifting the decimal point to the right. Thus if the span is 10 ft. and the sag is 0.6 in. instead of 6 in. the tension would be 105 lbs. instead of 10.5. If the span is 12 ft. and the sag 0.1 inch, the tension would be 907 pounds instead of 90.7. In case the actual span of the belt does not agree with the span given in the table it is a simple matter to "estimate" the tension from the table. For example if the span is 8 ft. 6 inches and the sag is 1 inch. The tension would be midway between 40.3 and 51. To find this midpoint add the two figures together and divide by two. The answer is 45.65. Another way is to subtract the two members (50—40.3) which gives a difference of 10.7 in. Then divide this by two (10.7÷2) and we get 5.35. Lastly, add this to the smaller number (40.3+5.35) and we get the same answer:—45.65 pounds per square inch.

FEED WATER CONTROL

"Regulating Boiler Feed Water" is the title of a booklet which has just been published by the Northern Equipment Company, Erie, Pa. The subject has been treated in an entirely new way, the object being to cover the subject of boiler feed water regulation completely and yet very briefly. To accomplish this purpose, free use has been made of a graphical method of presentation; charts showing the effect of feed water regulation on water input, steam output, feed water temperature, etc., also other charts, photographs, etc. There are only twenty pages and the booklet can be read in less than fifteen minutes.

POWDERED FUEL EQUIPMENT

The Combustion Engineering Co., New York, have issued in booklet form the paper read by Mr. H. D. Savage, relating to the powdered fuel equipment at the Rouge River plant of the Ford Motor Co. This is a very interesting description of an unusual installation, and includes the discussion following the reading of the paper. The bulletin is illustrated with views of the burners employed, as well as a cross section through the boilers, while at the back of the book is a reproduction of a typical steam flow chart, steam temperature chart, and stack gas temperature chart as obtained from the plant.

STOKER COMPANIES MERGE

The Sanford Riley Stoker Co. has merged its interests with the Underfeed Stoker Company of America and its affiliated companies, the A. W. Cash Co., valve manufaiturers, Decatur, Ill., the Craig Damper Regulator Co., Detroit, Michigan and the Underfeed Stoker Co., Ltd., of Canada. The products of the combined companies which include the Jones, Riley and Murphy stokers, make one of the most complete lines of mechanical stokers ever brought together. Manufacturing will be concentrated at Detroit, Michigan and Worcester, Mass., and in Canada at Windsor and St. Thomas.

Mr. R. Sanford Riley becomes president of the combined companies with Mr. F. H. Daniels as vice-president. Mr. S. A. Armstrong continues as vice-president and managing director of the Underfeed Stoker Co. of America.

Economical Design of Steam Piping

By ZUCE KOGAN

The factors that make the economical transmission of steam a complicated matter are the position and the variety of the steam using apparatus. Referring to the variety of machines, we have to consider that each one may possess different characteristics as to the pressure required, and the number of pounds of steam per hour consumed. This means that different diameters of piping are required, and perhaps different quality of piping for different machines.

Steam using apparatus is usually distributed in various parts of a factory. For instance in a sugar factory, the steam engines will be in one part, steam turbines in another, evaporators, juice extractors, driers, etc., all using steam and all in different portions of the plant. The question of economic installation of piping is therefore one that needs consideration, and convenience of repairing, and detecting leaks must be thought of when making the design.

Position of Apparatus

The position of the steam using apparatus is the chief factor which affects the piping lay-out. While it is not possible to arrange the apparatus to suit the piping, it is interesting to see just what could be done in this direction.

First, the machines could be arranged so that their steam connections will be approximately in one straight line. The main and branch pipes will therefore be as short as possible.

Second, the apparatus could be arranged around the boilers, as shown in Fig. 1. This enables the piping to be laid out in a loop form, which is a good way, as it enables any portion of the plant to be shut down while the rest is running.

Another method is that shown in Fig. 2, in which the steam using apparatus is placed around the outside of the building, and the non-steam-using machinery

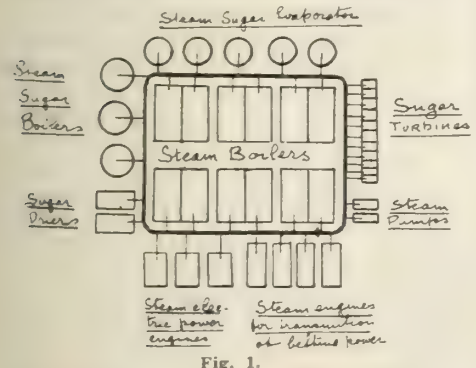


Fig. 1.

in the centre. This possesses the same advantages as the arrangement in Fig. 1.

The installation shown in Fig. 3, while good practice, is much more expensive than the other two, as it requires more branch piping, more losses following as a natural consequence.

Economy of Piping

Considering the piping itself, apart from the placing of the steam-using apparatus, we have to consider the relative lengths of main and branch piping.

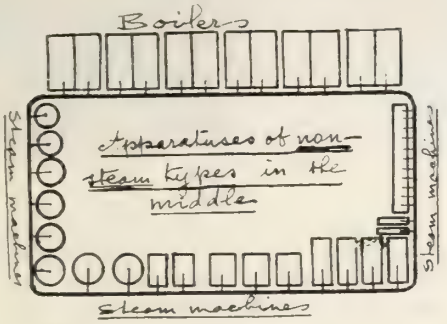

Fig. 2.

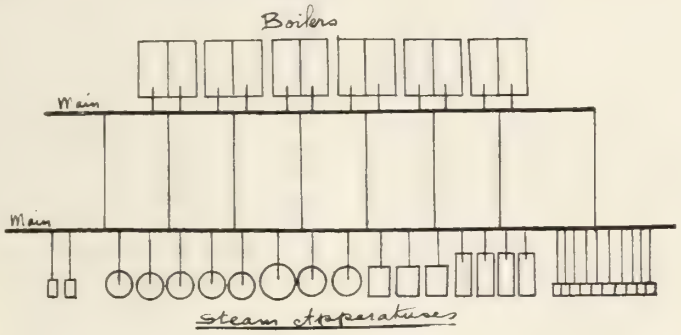

Fig. 3.

The relative cost of these two factors must be looked at from the point of view of initial and operating cost. Regarding the initial cost, the mains being of much larger diameter and weight than the branches, are more costly to buy, and also to install. Thus if initial cost only is to be considered, the natural thing will be to reduce the length of mains, and increase the branches, as their cost comes considerably below that of the mains.

When the working costs are considered it is different. The losses here to be considered are loss of power through drop in pressure due to friction, and loss due to radiation. These losses are greater in small than large pipes, and therefore from this point of view the better plan would be to make the mains longer and decrease the branches.

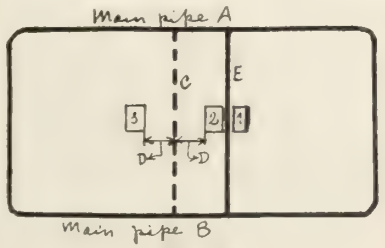

Fig. 4.

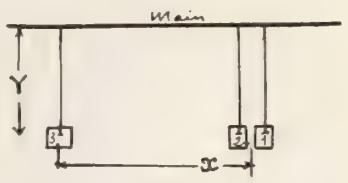

Fig. 5.

In an example like that in Fig. 4, we have three pieces of machinery to connect to the main. This could be connected as shown in Fig. 4, or by means of a loop. Having two distances to consider it is possible to calculate whether the losses of power would be greater with the branch or main piping. When x is small and y is very long, it is more economical to use the main as in Fig. 5. If y is small and x very long it will be obvious that it is bettter to install three branch pipes.

Fig. 5 is an example of a large factory with a main steam loop passing round the building. In the middle of the loop it is necessary to install three machines. These machines may be connected by three branch pipes, but suppose the distance is such as to require the installation of another main. This main would be run from one side to the other at right angles to the two mains. If placed in the position C it would require three lengths of branch pipe D, to connect up, while if the main is installed in the position E it will require only one length of branch pipe D, thus reducing the branch piping about 5 per cent. The economical lay-out of piping requires great study, and the application of the principles of geometry, if initial and working costs are to be reduced to a minimum.

The Atlas One Cylinder Pass-Out Engine

An Engine Developed for Working Economically in Plants Where a Large Heating Demand Exists in Comparison With the Power Requirements, by the Atlas Company, Copenhagen

Courtesy of The Engineer.

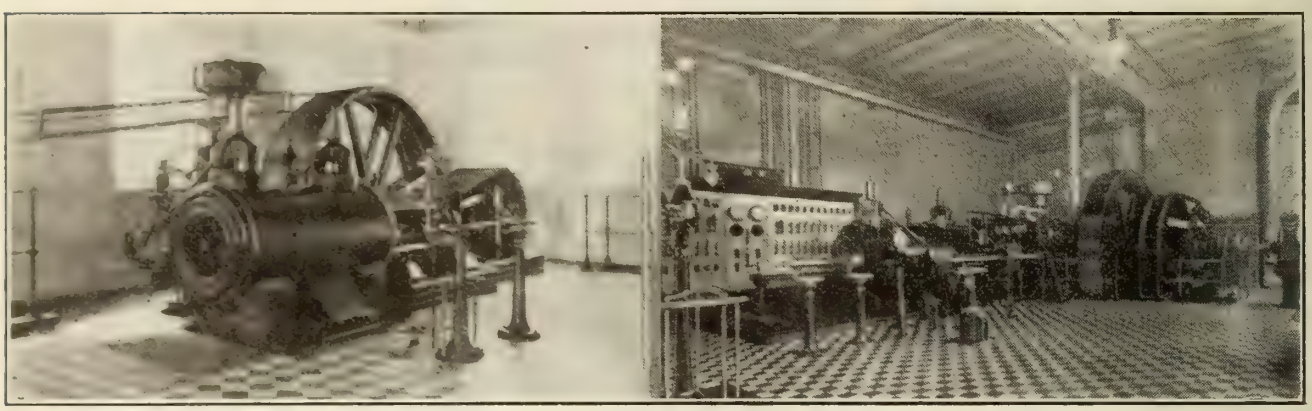

Fig. 1.

IN order to consider in any adequate manner the economical utilization of steam in industry we have to take account of many chemical and industrial processes in which, apart from its main function of furnishing power in a prime mover, a large quantity of steam is also required for heating and other operations. It is perhaps hardly necessary to emphasize that real economy can only be obtained where the two demands are satisfied, and at the same time means are provided to balance automatically the fluctuating loads which will undoubtedly be met with on both the power and heating systems. The advantages which accrue from an installation designed in accordance with these principles are recognized, and in the paper-making industry in particular the pass-out steam turbine is successfully employed. There remain, however, many cases in such industries as paper-making, brewing, dyeing, and the manufacture of chemicals and textiles, where for outputs up to 1,000 horse-power the modern steam engine may be used with profit. The advantage of the steam engine is perhaps most marked where, say, in the case of a brewery, the proportion of power required is small compared with the steam needed for heating, and again where steam for heating is exhausted to the mains at two different pressures.

The problem of the pass-out steam engine has been carefully studied by the Atlas Company, Limited, of Copenhagen, which has, especially during the last few years, supplied a large number of such engines for use in factories in Denmark and Scandinavia, where, on account of the high price of fuel, rigid economy in its use is necessary. The type of engine most frequently adopted is the single-cylinder drop valve design, with a special valve gear, and engines of this pattern have been constructed in sizes varying from 150 horsepower up to 1,000 horsepower. For larger powers two cylinders may be employed. Before describing the patented arrangement of valve gear on the Atlas engine, we may call to mind the conditions under which the normal steam engine works when exhausting steam to heating mains against a fixed back pressure. Unless some regulating device is introduced it is difficult to control the load on the engine so that the exact quantity of steam is admitted to and exhausted from the engine and in nearly all cases uneconomical working cannot be avoided, because any shortage of exhaust steam must be made up by passing additional high-pressure steam into the system through a reducing valve, or, on the other hand when exhaust steam is delivered in excess, any surplus is exhausted to atmosphere through a loaded relief valve.

Valve Gear

The object of designing a pass-out engine is to attain maximum economy of operation by so balancing the load on the two sides of the piston that, on the one side, only the exact quantity of steam required for heating is admitted to the cylinder and exhausted to the condenser or a second heating system. Fig 1 illustrates a 280 horsepower single-cylinder engine working with steam extraction, and in Figs. 3 and 2 we reproduce a section through the engine cylinder and a detailed drawing of the arrangement of the automatic exhaust valves. It will be noted that valves are accommodated in separate end covers, and that the cylinder is a plain casting. Steam is admitted through inlet valves A and B, and is discharged through the exhaust valves C and D to the heating mains E and F. If the engine is fitted for condensing, the simple jet condenser is usually employed, with the air pump driven from the main crank shaft. Control and isolating valves are provided, and the exhaust steam connection to the condenser may be taken from pipe E. The general disposition of the valve gear is indicated in Fig. 4. Double-seated drop valves are employed, and they are operated in the usual manner by excentrics on the horizontal lay shaft. The cut-off is regulated by the speed governor, which controls the opening of the inlet valve, alternating the position of a curved lever which moves between rollers, and is attached to the excentric rod. In addition to controlling the speed of the engine, it is also desired to balance the exhaust steam and power loads, and this is done by turning to account the variation of steam pressure in the heating mains, which variation is used independently to control and to alter the cut-off in that half of the cylinder which is dealing with the heating steam. Thus, when a sudden demand for exhaust steam reduces the pressure in the heating main, the cut-off in one half of the cylinder is automatically lengthened, thereby admitting more steam, but at the same time the cut-off is reduced in the other half of the cylinder, and the balance is thereby maintained. Adjustment may be effected either by hand or by means of a special governor, which is directly controlled by the variation in pressure in the heating system.

We show, in Figs. 5 and 6, the arrangement of the governing gear for a single-cylinder engine with hand adjustment. The lever A on the speed governor is connected by the rod B to two links C, the position of these links being determined by the load on the engine. A block D is provided on each set of links, and this block is capable of independent adjustment by means of a screwed spindle operated by the hand wheel E. The movement of the link block alters the position of the excentric F, which, in turn, varies the cut-off by controlling the inlet valve. The excentric positions for each half of the cylinder may be varied independently, but both are simultaneously governed by the speed gov-

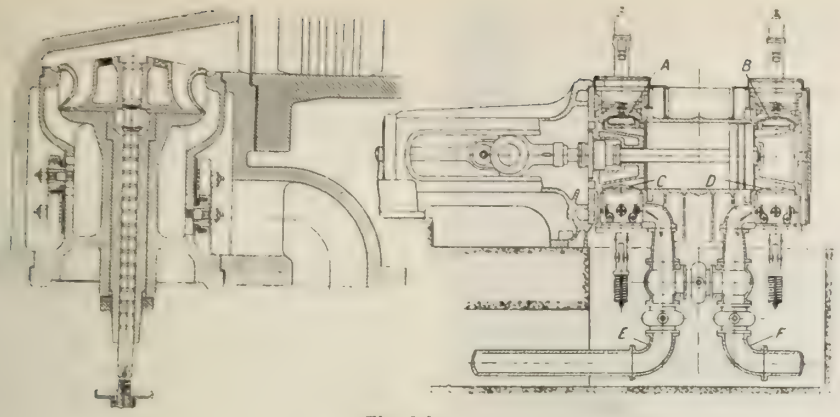

Fig. 2-3.

ernor. In order to prevent the engine racing, should the load at any time be suddenly thrown off, the links are so shaped that the excentric gear will cut-off at zero when the speed governor is in its highest position, regardless of the position of the link blocks in the links. The sketch reproduced in Fig. 7 illustrates diagrammatically the same governing device, but instead of hand adjustment, a special governor is provided which regulates the cut-off automatically. The lettering used in Fig. 7 is the same as that in Fig. 5, and the letters have the same signification, but the additional parts are the steam pressure governor G and the two governing shafts H which operate the excentric gears controlling the inlet valves. It will be seen that the position of the moving parts of the steam governor G is determined by the pressure of the heating steam, and this, in turn, is dependent on the amount of steam passing to the heating mains. Should the load on the engine suddenly increase and cause an amount of steam to pass in excess of the predetermined quantity of exhaust steam, the rise in pressure will cause the piston of the governor to lift, and by means of the double lever the top block D will be moved forward and the bottom block D drawn back. The mechanism is so arranged that the movement of the top block forward reduces the cut-off in that half of the cylinder supplying heating steam, and the simultaneous movement of the bottom block in the opposite direction increases the cut-off on the power side of the cylinder. By this means the quantity of steam which is exhausted to the heating main is kept constant—unless it is varied by hand—and the balance of steam required to meet the load on the engine is exhausted to the condenser in the most economical manner.

The action of the governing gear will be clearly seen from the series of indicator diagrams reproduced in Fig. 9. The set of indicator cards here shown were taken from an engine of the type we have just described, and it will be noted that the cut-offs vary considerably in the two halves of the cylinder as the demand for exhaust steam changes. The cards marked B are taken from that half of the cylinder which is working against back pressure, and is delivering steam to the heating main, and those marked C are taken from the half of the cylinder which is working on the condenser. The horsepower developed by the engine is approximately the same in each of the three cases. Attention may be called to the bottom left-hand card, which represents the conditions obtaining in the back-pressure side of the engine cylinder when working with a very small cut-off. Even under these unfavorable conditions practically no loop is shown. This result is made possible by the specially designed exhaust valve which we have previously referred to and which is shown in detail in Fig. 2. The feature of this valve is that a series of non-return valves are placed close against the main exhaust valve, and in this way the steam is prevented from getting back into the cylinder. A marked improvement in working is shown if the two lower cards marked B are compared with card A, which was taken from the same engine working with the exhaust valves of the old design. With the old design of valve the loop is very marked, and the resulting loss considerable.

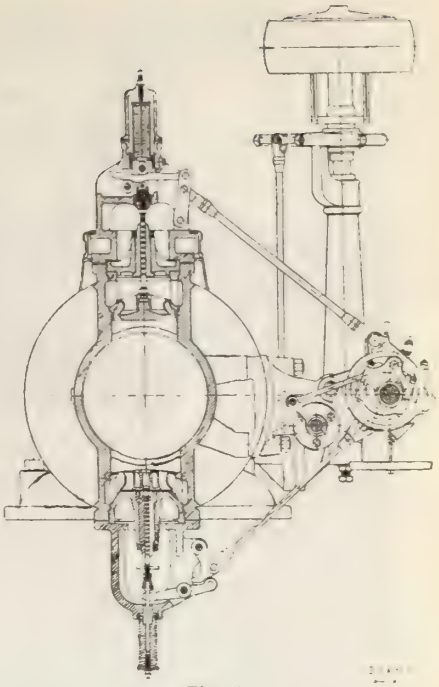

Fig. 4.

Log of a Trial Run

The maximum back pressure against which a passout engine is capable of working is fixed by the initial steam pressure, and engines are generally built for back pressures varying from 7 lb. to 50 lb. per square inch pressure. For a back pressure of 50 lb. per square inch an initial pressure of 160 lb. to 170 lb. per square inch is required. The steam consumption varies according to the sizes of the engines and the conditions under which they have to work. As an example we give the following report of the final tests of a 280 indicated horse-power Atlas one-cylinder type pass-out steam engine, which was recently installed at the Soda Works, Limited, Copenhagen.

GENERAL PARTICULARS

Diameter of cylinder..... 19.75 in.

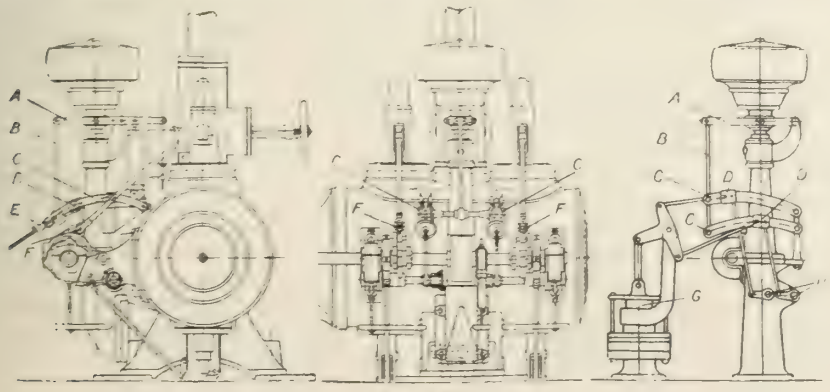

Fig. 5-6-7.

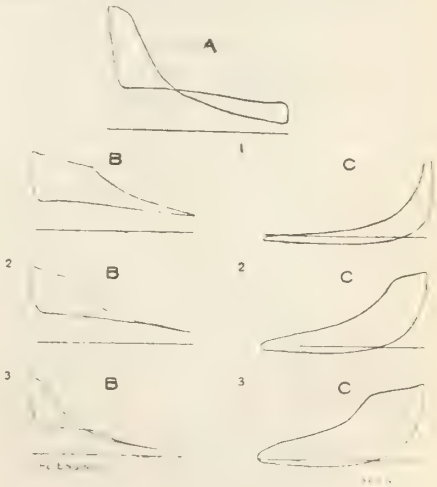

Fig. 9.

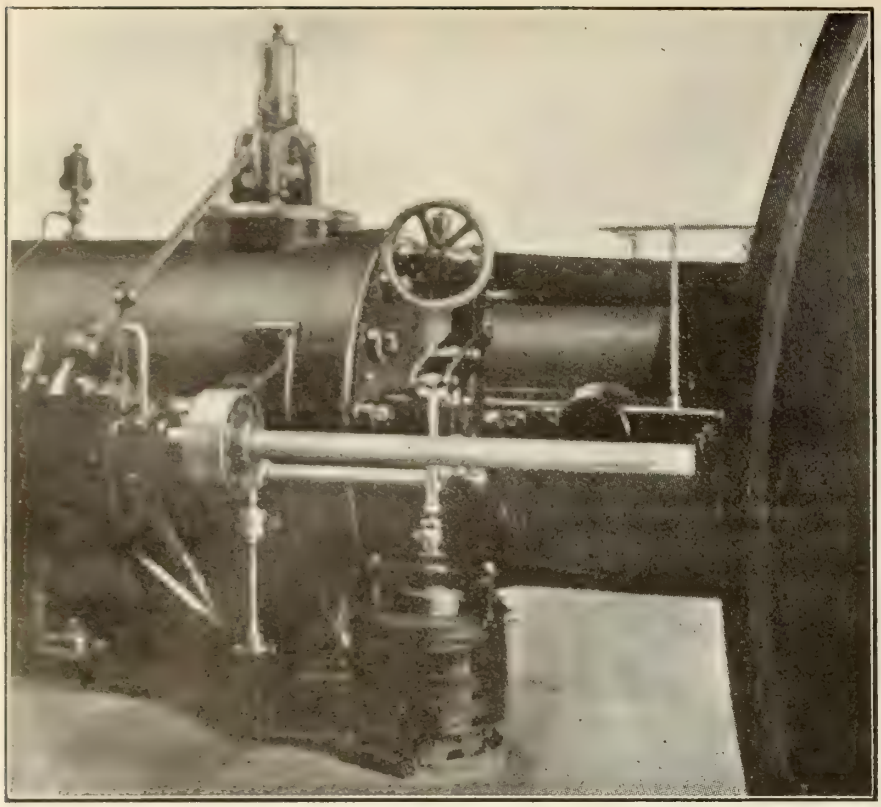

Fig. 8

Stroke	27.5 in.
Speed	150 r.p.m.
Normal load	280 I.H.P.
Maximum continuous load	375 I.H.P.
Boiler pressure	145 lb. per sq. in.
Total steam temperature at engine stop valve	605 deg. Fah.
Type of condenser	Jet condenser
Temperature of cooling water	70 deg. Fahr.
Vacuum average with barometer at 30 in.	26 in.
Pass-out steam pressure	42.5 lb. per sq. in.

The following steam consumptions were guaranteed:—

	Full load	Three-quarter load	Half load
Pass-out cylinder half, pounds, per I.H.P.-hour	35	37	43
Condensing cylinder half, pounds per I.H.P.-hour	12.8	12.8	13.6

The mechanical efficiencies were:—At full load, 92 per cent.; at three-quarter load, 89 per cent.; and at half load, 84 per cent. The engine was designed so that under normal conditions the front half of the cylinder works condensing and the back half of the cylinder against a back pressure of 42½ lb. per square inch. As we have already described the load on the two cylinder halves is regulated by a steam-pressure governor operating on the eccentric gears, and controlling through these the inlet valves, so that by varying the cut-off the exact quantity of steam required for heating purposes is admitted to the cylinder half working with back pressure, and the balance of power required is developed by the half of the cylinder which is working condensing.

For the purpose of testing the engine, two trials, each of approximately four hours' duration, were run, the first one with both cylinder halves working condensing and the second with both cylinder halves working against back pressure. We append particulars and results of these two tests.

Test I.

Boiler pressure	128 lb. per sq. in.
Pressure at engine stop valve	126 lb. per sq. in.
Total steam temperature	575 deg. Fah.
Temperature of cooling water	70 deg. Fah.
Vacuum (barometer 29½in.)	25.25 in.
Speed	146.4 r.p.m.
Indicated horse-power	197.2
Total steam consumption, per hr	2,160 lb.
Steam consumption per I.H.P.-hour	13.2 lb.
Steam consumption per I.H.P. hour, corrected for 145 lb. boiler pressure and 605 deg. Fah. steam temperature	12.8 lb.

Test II.

Boiler pressure	124 lb. per sq. in.
Pressure at engine stop valve	120 lb. per sq. in.
Total steam temperature	577 deg. Fah.
Back pressure	42.5 lb. per sq. in.
Speed	143.9 r.p.m.
Indicated horse-power	155.0
Total steam consumption per hr.	6100 lb.
Steam consumption per I.H.P-hr.	39.4 lb.
Steam consumption per I.H.P.-hour, corrected for 145 lb. boiler pressure and 605 deg. Fah. steam temperature	34.4 lb.

We show in Fig. 8 an illustration of a 750 brake horse-power single-cylinder pass-out engine working in a large brewery.

A HANDY REPAIR

The following little experience may be of use to some other engineer in a similar case, and is given for what it is worth.

A cross compound Corliss engine had just been installed, and had run its preliminary trials, when a part of the joint of the low pressure head at the crank end blew out. To remove the head and make a complete new joint would have meant a lot of work, besides running the risk of throwing everything out of alignment again. The following plan was therefore adopted.

Litharge and glycerine were pumped in around the bolt hole where the joint had given out, by means of a force pump. This was allowed to set, and the job again put into operation, when it was found the joint was tight and satisfactory in every way, and the engine is running at present with that repair.

HOLIDAY BOILER CLEANING

By "Jimmie"

A subject which should be of interest to owners, superintendents, managers, etc., as well as the engineer, is the question about the time-set boilers. I refer particularly to the small plant containing only two or three boilers. I believe it will be admitted that cleaning is often set for a public holiday, the owners, or whoever has the fixing of the time, think they are saving a day by following out this dangerous practice. It can be dangerous as it is certainly very bad business under certain conditions. Sunday cleaning is bad enough considering the practical side of the question only as the firing can be discontinued at noon Saturday and the boiler and brickwork will have a chance to cool down considerably by Sunday morning and there are big chances that the average engineer or cleaner will do an honest job even if his inclination is against Sunday work. But when a fire is kept going until the evening preceding a holiday and the boiler cleaned out on the holiday, it is very often cleaned in name only. A boiler cleaned in a hurry by a discontented man is not cleaned at all as a rule. I believe the boilers in a plant where the public holiday cleaning act is in force will soon acquire a pretty thick coat of scale or worse. Neglecting to consider the question of fuel waste there is the danger of burned plates and the impossibility of noting defects such as pitting, etc. The cost of the fuel waste in such a condition even when there is only one or two boilers would, in a few years, pay the cost of a new boiler and for the installation of it. How can an inspector give an unqualified report of a boiler's condition in a case of this kind? About the only thing he can be certain about is the coating of scale. Really necessary repairs are often ignored in plants where the boilers are only out of service on public holidays and if the repairs are attempted at all they are done in an inefficient, hurry-up way because the men are eager to get away. Holiday cleaning like holiday inspecting is never as satisfactory as when done at other times. The discomfort of boiler cleaning and inspecting is great at any time, these discomforts are usually accentuated on the public holiday plan on account of the great heat and if preparing for the inspector the external cleaning as well as the internal is apt to be hurried and imperfect. If the inspecting is done on the holiday nobody may be at hand should the inspector require service. Much more could be written against this public holiday habit but I think a little consideration will convince most folk that boiler cleaning and boiler inspection should never be hurried under ordinary conditions. Either job is likely to be a hurry-up one when done on a week day holiday.

Overcoming Heavy Costs of Belt Maintenance

Transmission Problems Should be in Charge of Competent Man —Inspection Should be Made Regularly—Importance of Proper Alignment—Lacing of Joints Should Be Carefully Performed

By J. H. RODGERS

ECONOMICAL production under modern competitive conditions is largely a matter of getting the most out of plant and equipment. Machinery, tools and appliances are for the most part carefully purchased and industriously kept in good working order after installation, yet in mills where the greatest care is exercised in the constant maintenance of machinery, little or no attention is paid to the upkeep of transmission belting. The result is a loss in power and production so serious that it frequently causes a very appreciable loss in profits. Satisfactory operation of any system of mechanical power transmission depends upon the care with which the belting equipment is selected and cared for after installation. Yet so general is the efficiency in most mills that the extent of loss in production through this item is seldom realized.

Saving Power Wasted

The power that is produced is that actually delivered to the machine pulley—and the power that is costly is that which is lost somewhere between the boiler and the belt on the driven pulley. Much of this wasted power can easily be saved by constant, careful attention to the upkeep of the transmission system. A good share of power loss is caused by neglecting to keep belting in first-class condition; by failure to tighten loose belts, to dress dry belts and to repair worn-out belts. Part of this failure is due to the fact that the loss is not often recognized by mill superintendents and master mechanics. The greater part, however, is due to the fact that anyone in the average mill looks after the belts on his own machine or in his own room.

No one would think of running a mill without a competent man to take charge of and repair machinery. Why then expect the belting on which those same machines are directly dependent to operate with little or no skilled attention? The first move to cut down transmission costs, reduce power losses and eliminate break-downs should be the placing of one man (on each shift, if necessary) in complete charge of all transmission equipment—shafting, pulleys, hangers and belting. Put him in absolute control and hold him to the responsibility. Allow no installation changes, repairs, or dressings except by him or under his direction. This arrangement is advisable for two reasons. First it insures the equipment of constant attention so that repairs are made when needed and not two weeks later as is often the case. A stitch in time is particularly true in the case of belting. Then second, it ensures, so far as may be, uniform treatment of the belting—a very desirable factor in increasing belt- life and in lessening the chances of breakdowns and loss production.

Experienced Supervisors Necessary

When possible, it is desirable to put an experienced man on the job, but where this is impossible, a man should be selected and given a short course of training in a belt factory, where he will learn how to make laps, take up belts, repair and dress belts, etc. A week or ten days in any good belt shop will go a great way toward transmission efficiency in the mill. Most belt manufacturers are glad to allow a man to spend this time in the factory, learning the rudiments of belt making. A mill should be provided with the necessary equipment for doing all ordinary belt work—breakdowns and tie-ups are too frequent and too expensive to depend on outside repairs. The tools ordinarily required are clamps and rods (for holding belt when cementing endless), belt scraper, belt shave, slicker, spoke shave, hand punch (for lacing holes), cement, brush, and kettle for melting the glue. These tools can be supplied for a reasonable amount from any mill supply dealer or belt manufacturer.

Regular Inspections Needed

After placing your belt man in charge, see that he makes a regular inspection of every belt in the mill at least every two weeks. This systematic inspection should cover such points as general conditions of belt, need of dressing or of cleaning, tension, condition of laps and joints, amount of belt slip, amount of wear, etc. Pulleys and shafting should be carefully watched to see that they are in strict alignment. In many mills it has been the practice to have regular reports made of such inspection—but this does not always pay, except in the case of large mills with hundreds of drives. Experience has proved that constant, systematic inspection of all shafts, belts and pulleys, by a competent man, followed up by prompt attention to all necessary repairs, will reduce belting bills from 10 to 20 per cent. while practically eliminating any unexpected delay through faulty power transmission. All trouble with the belting in the plant should be immediately reported to the belt man, and he should be held responsible for the continuous operations of every machine in the mill.

The second point in economical operation of a power transmission system is the standardization of belting for each drive. This merely means that

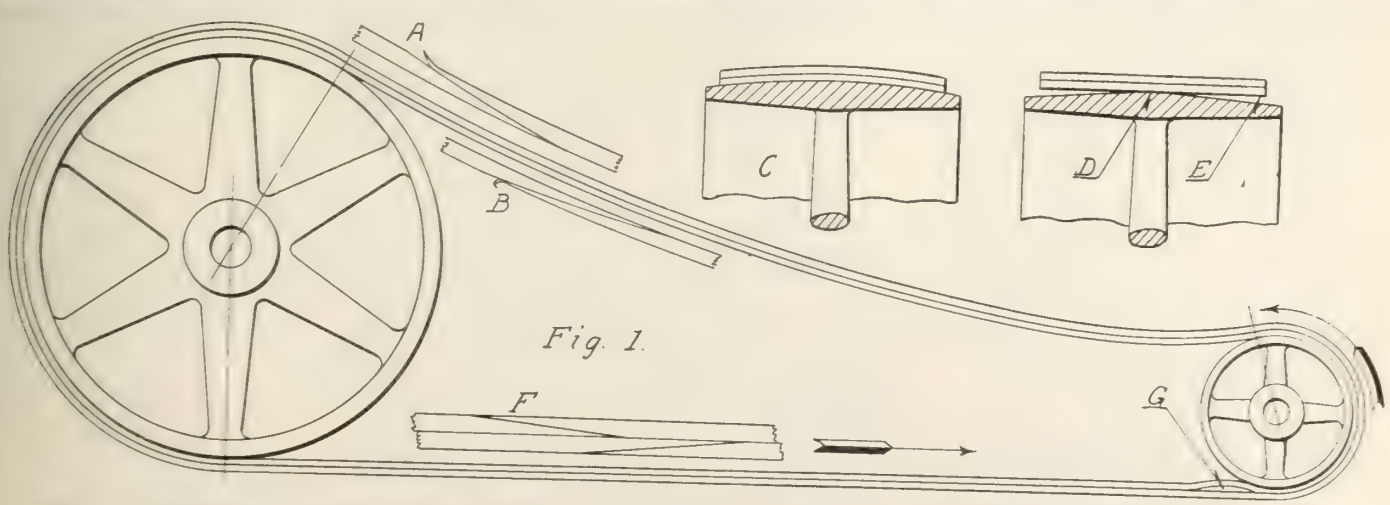

Fig. 1.

Fig. 1.—A. Thin edge of cap curling from air pressure. B. Curl from pulley contact. C. proper method of crowning pulley. D. Avoid sharp crown. G. Ply lifting due to creep.

for every drive there is one type, brand, ply, width and weight that will work out most efficiently. Find out as nearly as possible what that belt is—and order it for that drive when necessary. The standardizing if applied with a fair measure of common sense and not carried to extremes, will amply repay the time and effort spent on it.

Belting should be purchased with the due regard to the mechanical and physical condition of the drive. The main things to keep in mind when ordering belting are; diameters, faces and speeds of pulleys, type of drive (open, crossed, vertical, etc.,) centre distance between pulleys, load to be carried, and the atmospheric conditions (dust, steam, fumes, etc). Pulley diameters control the weight or thickness of the belt to be used; belt speed controls the power that can be transmitted by the belt; load to be carried determines belt width; type of drive and physical condition determine the type of belting best suited.

Nor is it always necessary to specify first-quality belting of any particular type. Where the work is light or the pulley large or the speed low, second quality belt can often be used with just as satisfactory results as higher priced brands. When the best type, ply, width and weight for any drive have been determined by the belt man, make a record of it for the use of the purchasing department or for the superintendent. Always specify the standard instead of "using what you have left over" from other work—it pays better.

Proper Tension

The third item to watch out for is belt tension. The tightness with which belts are put on pulleys is of prime importance. If a belt is too tight, there is a large loss of power from excessive friction at the bearings, to say nothing of the fact that the belt itself is overstrained and weakened. On the other hand, if a belt is too loose, it is liable to flop around and jump from the pulley, particularly when working where a load is suddenly thrown on or off. If too loose, there is sure to be unnecessary slip and loss of power as well. When belts are installed and taken care of by one man, the errors of too tight and too slack belting should be avoided and a uniformity of tension will result, which could not be secured as easily in any other way.

Aligning Shafts and Pulleys

Fig. 2 shows a simple method of lining up two pulleys. The operator, with a helper, takes a piece of cord and stretches it from the outside edges of the two pulleys just above the shaft or hubs if the latter extend beyond the edge. With this method it is understood that the shafts have been lined up previously and that the pulleys run true. When using the string it is well to try the pulley in several positions to allow for any irregularity in run of the pulley.

Crowning of Pulleys Important

Steady running of belt is essential to effective transmission. For continuous drives, belts are generally run on pulleys that are very little wider than the belt, and to maintain its position in the centre, the pulleys are invariably crowned. This crowning usually consists of two straight tapers meeting at the centre of the pulley face. The amount of the taper varies from ⅛ to ¼ inch per foot; that is, a pulley 12 inches wide would be about 1-16 inch larger in diameter in the centre than it would be at either edge. In a straight taper crown, however, it will be seen that the apex D, Fig. 1, forms a definite or pronounced breaking point; nothing very serious possibly, but with a tendency, especially in new and heavy belts, to provide an air space at the edges E. A better plan of pulley crowning is that shown at C, where the surface forms an arc; this method equalizes the bending stresses throughout the width of the belt and makes the surface contact more uniform.

Preparing Belt For Lacing

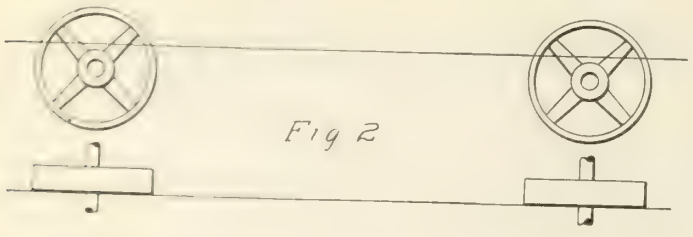
One of the essential factors of a belt joint is that the ends should be perfectly square with the run of the belt, to assure its smooth running. When cutting a belt the use of a try square, as shown at A, Fig. 7, is always advisable. Without such a tool the tendency is to make an angular cut as at the right, so that when the joint is made it has the appearance as illustrated at B. When passing over a pulley the belt develops a tendency to oscillate, and such a condition is very much aggravated when the belt is running a little loose. To prevent it jumping off, a stick is frequently secured to some rigid support and extended down at the side of the pulley. This, however, provides only a temporary remedy for a previous fault, as the weakest portion of the belt—the laced joint—is continually brought into violent contact with this "guide" and eventually the efficiency of the drive is destroyed.

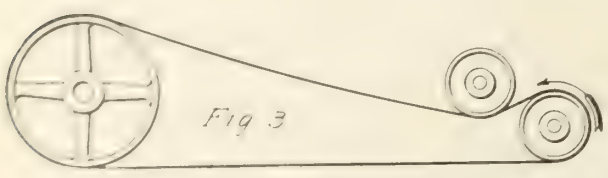
Making a Laced Joint

In making a joint it is advisable to use a thin lace in preference to a thick one. This coincides with what has been said on belt contact, as it is clear that the thicker a lace is the less will the contact be when the joint is passing around the pulley, and in addition the jar will be all the more pronounced. When making a joint the straight lacing should be made on the pulley side. Owing to the different widths of belts no fixed rule can be applied for lacing, but in general the method may be the same for every case. Holes should not be closer to the edge or end than one-half inch, with centre holes spaced accordingly. The best practice is to commence at the centre and work out and back on each side. As a guide the illustration Fig. 4 is given. Starting at 0 and 1 the order is as follows: 2, 3, 4, 5, 4, 3, 2, 1 or 0, both sides of the centre being identical; the locking is performed by passing the free end through a small hole 6, and cutting a short slit to form a hook that will prevent the lace from coming out. This lock should be on the outside of the belt. After the joint is made it may be lightly hammered down with a wooden mallet.

Use Small Lace Holes

It must not be taken for granted, however, that all one has to do is to cut off a piece, punch a few holes and secure again with a lace, to obtain an effective drive. The fundamental details of a properly made joint may often seem of little import, but the subsequent





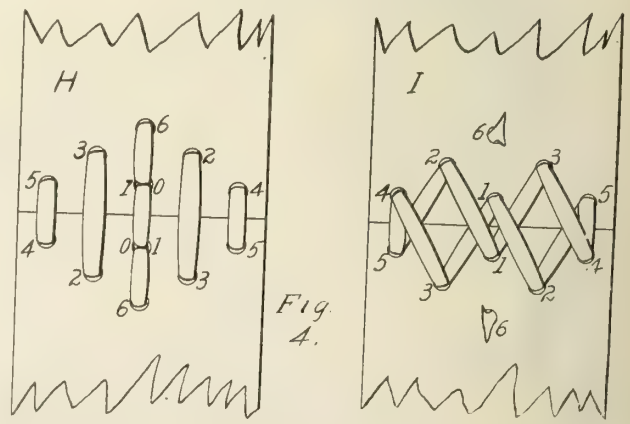


Fig. 2.—Aligning pulleys with string. Fig. 3.—Position of idler. Fig. 4.—Showing effective method of lacing belt, straight lacing on pulley side.

operation of the belt may depend, very largely on the consideration given to these apparently insignificant matters. When making a repair to a belt the beginner will usually make the lace holes of large size as indicated at centre of Fig. 5. The inevitable consequence of such practice will be that shown below at the left. With very few exceptions, a belt will tear across the lace holes and seldom will fail in a direction parallel to the belt length. For this reason it is imperative that the amount of the leather cut be kept as low as possible, consistent with the size of the belt and the thickness and width of the lace. Where it is necessary to enlarge the holes it should be done as shown at the right. This is obvious when comparing the resultant efficiency of the belt in each case. The short light space indicates the portion of the width cut away by the holes and the dark portion the effective section of the belt.

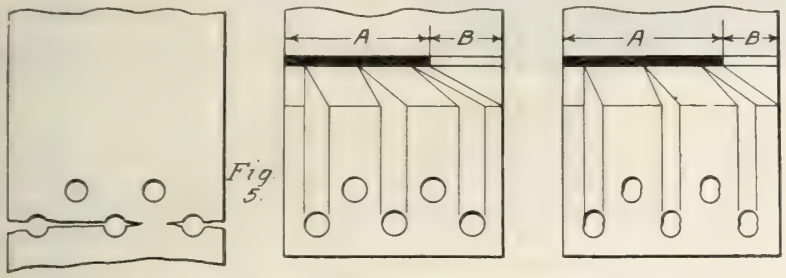

Fig. 5.—Effect of having lace holes too large.

The best side of the belt to run upon the pulley appears to be a debatable question, as many favor the hair or smooth side, while others prefer the reverse. However, as the efficiency of a belt drive relies on the frictional contact between the surfaces it would seem practical that the smooth side would have the preference. Another factor in its favor is that of the recognized fact that the portion of the belt best suited for tensile strength is near the flesh or rough side, and the hardest side best adapted for the compression action; these features being quite evident when belts are operating on small pulleys.

It is evident that the slacker a belt can be run, up to a certain point, and do its work satisfactorily, the greater the economy. In installing belting and in taking it up, consideration must be given to the fact that certain kinds of belting are affected by atmospheric conditions, lengthening and shortening according to the amounts of moisture in the air. Water-proof leather belting, properly made, does not stretch much even when working in moist air for a long period. The best tension at which to operate a belt is that at which the belt will carry its load easily without straining and with a minimum of journal friction. Operate all belts just as slack as possible without slipping. When it is necessary to operate a leather belt tight on a drive to carry the load, that is a sure indication that there is something wrong with the drive which should be investigated and remedied.

High Tension

With an intermittent load, or one which varies greatly, it may be necessary to instal and operate belts at high tension. Bearings and shafting of course play a part in the amount of tension which can economically be used. For example, a belt can be installed with a greater tension on a self-aligning bearing than on a rigid pillow-block bearing. Again, a belt can be installed at a greater tension of a 23/16 in. shaft than on a 15/16 in. shaft. Belts which operate under a heavy load or which are travelling at high speed, usually require taking up every six months or so. Failure to do this means great waste of power through belt slip. When a belt runs suddenly to one side, after running straight for some time, it may be laid to sudden overload, or belt too loose. It may be necessary to reduce the load and tighten the belt. Where the required tension cannot be secured normally, idlers are used, both to increase the arc of contact, and to increase the tension. See Fig. 3.

Fourth: Eliminate injurious dressings and use a little good dressing sparingly. This is perhaps the most neglected item in the care of belting—and one of the most important. Belt dressing is necessary either when a belt is slipping badly for no apparent reason or when in the case of leather belting the natural oils have dried out of the leather, leaving the belt dry and harsh.

(To be continued)

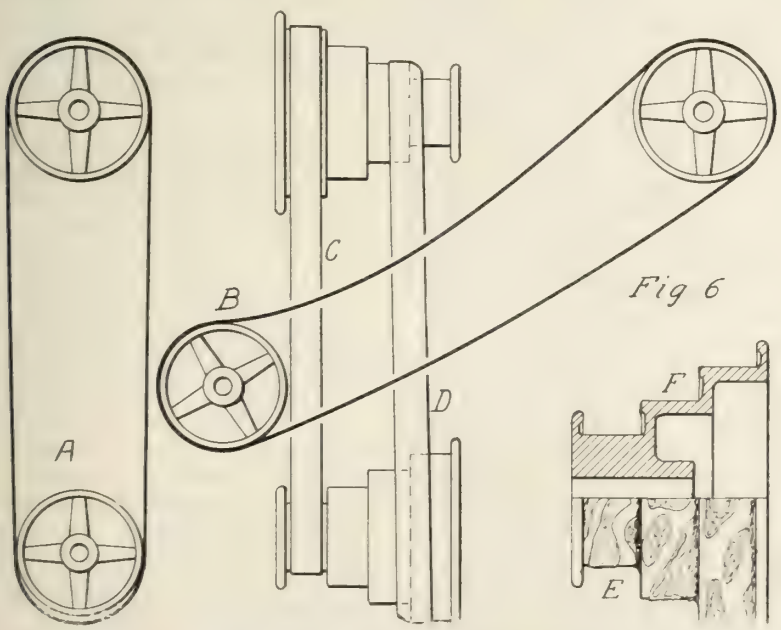

Fig. 6.—Vertical belts must be kept tight. D shows a serious fault on cone drive. E shows abnormal use of belt dressing.

RILEY INTERESTS ACQUIRE UNDERFEED STOKER CO.

The Sanford Riley Stoker Co., Ltd., Worcester, Mass., has acquired control of the stock of the Underfeed Stoker Co. of America, Detroit, and its subsidiary companies, the A. W. Cash Co., Decatur, Ill., the Craig Damper Regulator Co., Detroit, the Underfeed Stoker Co., Ltd., of Canada, the Craig Damper Regulator Co. of Canada, and the A. W. Cash Co., of Canada, Ltd. The Underfeed Stoker Co. is the oldest manufacturer of underfeed stokers for power boilers.

R. Sanford Riley, President of the Sanford Riley Stoker Co., becomes president of the Underfeed Stoker Co., and its subsidiaries. S. A. Armstrong, Detroit, will continue as vice president and managing director of the Underfeed company. By the consolidation Mr. Riley becomes president of nine companies, the five acquired in the merger, together with the Sanford Riley Stoker Co., the Sanford Riley Stoker Co. of Canada Ltd., the Murphy Iron Works and Murphy Iron Works Co. of Canada, Ltd.

The capital stock of the Riley company is $1,250,000 which, together with the $1,000,000 of the Underfeed company, makes a total of $2,250,000.

Headquarters of the merged companies will be in Worcester. The product of the Underfeed Co. will hereafter be manufactured at the plant of the Murphy Iron Works, the Detroit branch of the Riley company. The Cash company makes valves and valve specialties and also at these works is produced the Craig Damper regulator.

The Inter-Provincial Boiler Law

THE INTER-PROVINCIAL boiler code is now a fact, and is in use in the larger number of the provinces of the Dominion. The regulations have been set out in book form, and are now available to the public, at a price of $1 per copy.

It is interesting to note, that the first conference held at which representatives of the different provincial governments were present, to consider a uniform law, was as far back as 1909. The provinces represented on that occasion were British Columbia, Alberta, Saskatchewan, Manitoba and Ontario. The regulations drawn up at that conference were adopted by the provinces of Alberta, Saskatchewan and Ontario.

The regulations then adopted, while good in their way, were not comprehensive enough, and left many points uncovered, so that there naturally arose differences of interpretation. Owing to this, a further conference was held in Ontario in 1914, at which the regulations were revised and amendments recommended, but owing to the outbreak of war, and the general disorganization which followed, these recommendations were not officially adopted.

Nothing more was done until 1918, when a further meeting of the interested provinces was held in the Manitoba provincial buildings, at which the whole question was thoroughly gone into, and consideration given to suggestions which had been put forward by manufacturers, boiler makers, etc. The regulations as drawn up at this meeting were submitted to the Boiler Code Committee of the Engineering Institute of Canada, the Canadian Manufacturers' Association, and others for criticism. After this, a meeting was held in New Westminster in 1920, at which final revision of the code was made after studying the reports received. It will thus be seen that from the time of the first consideration of this question until its final adoption a period of thirteen years has elapsed. Of course, there is no doubt that the war threw things back to some extent, but in any case, it is evident that at least eight or nine years would have been consumed in effecting this very desirable reform.

It is an excellent thing from the point of view of the boiler manufacturer, and also of the boiler purchaser. It ensures the manufacturer the opportunity of building a boiler that will comply with the regulations in any province, while the purchaser has no fear of buying a boiler in Ontario that will not pass inspection in Manitoba, or vice versa. The regulations adopted have also provided for the use of boiler material which has been made to the specifications of the British Board of Trade, so that a manufacturer importing his plates, or a firm importing boilers from Great Britain will not be penalized.

Practically every province with the exception of New Brunswick and Prince Edward Island have adopted these regulations, and it will most likely be but a short time until they are in force in these latter provinces. The advantages of uniformity are too many for them to be neglected by any modern government department or private business concern.

The Pass Out Engine

IN ANOTHER part of this issue of "Power House" will be found a description of an engine being manufactured in Europe, which has some points that should make it of interest to steam users in this country. The engine has been designed to fulfill the dual purpose of supplying power and heat, such as engines are doing all over Canada every day, but in this case, there is a more elaborate arrangement than the simple weighted back pressure valve to keep a required pressure in the heating mains.

Briefly, the design is such that while one side of the piston is operated by steam exhausting to a condenser in the ordinary manner, the other side of the piston is connected to the heating mains. On the latter side control is effected by a governor operated from the pressure in the heating mains, and so arranged that if there is a demand for more steam in these mains, the cut off is lengthened on the side which is in communication with them, and shortened on the side in communication with the condenser which thus makes the total power the same.

It has been found that with this type of engine very economical working can be obtained where the power load is so much less than the heating load. These engines are made in sizes to 1,000 h.p. in one cylinder, thus making a compact arrangement.

The high cost of fuel in the districts where this engine is in use was the immediate cause of its adoption, and we should think there are many places in this country where something of the same kind could be used to advantage. We have the high cost of fuel with us, we have also the necessity for heat during a large portion of the year, and for process work during the whole of the year. There are many firms still buying electric power and burning fuel for heat at the same time. It is only in exceptional cases that there is any real saving in following this course. Even with the ordinary relief back pressure valve method of heating, or the bleeder turbine, power and heat can be obtained from practically the same amount of fuel as heat alone requires. With an engine built along the lines described still better results should be obtained than are now possible.

Progress in New Equipment

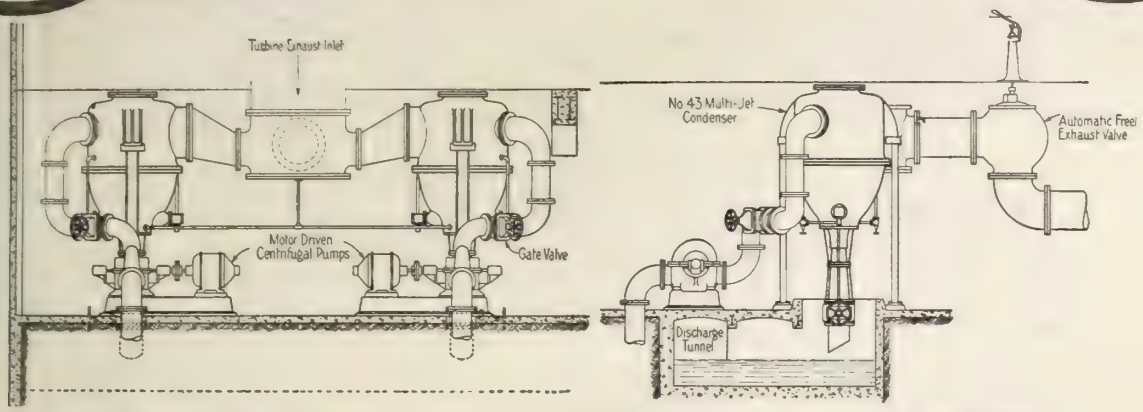

Fig. 1. Diagrammatic arrangement of the twin low-level multi-jet condenser installation at the Baltimore Consolidated Gas, Electric Light & Power Company.

A TYPICAL LOW LEVEL MULTI-JET CONDENSER INSTALLATION FOR CENTRAL STATION SERVICE

By A. L. Penniman*

IN JANUARY, 1921, the Consolidated Gas, Electric Light & Power Company, of Baltimore, installed two No. 43 Schutte & Koerting low-level multi-jet condensers to serve a 9,000 K. W. General Electric turbine.

A most interesting feature of this twin jet condenser installation is its simplicity. The customary removal and air pumps are dispensed with—the air non-condensable gases and water being removed from the condenser by the cooling water on the ejector principle. The only pumps required are two standard motor-driven centrifugal Cameron pumps** for supplying the injection water to the condensers. A plan and elevation of the installation are given in Fig. 1.

The manufacturer's guarantee was 28.25 inches vacuum referred to a 30-inch barometer at full load with 70 deg. F. injection water. In the acceptance test, the guarantee specified was exceeded by 0.08 inches. Because of the value of the test results obtained and their significance as to what can be expected of jet condensers of this type under the conditions existing in central station service, the test referred to is given in detail.

A sectional elevation of the low-level multi-jet condenser is shown in Fig. 2. It consists of a condenser body or closed cylindrical chamber, the upper end of which contains a water nozzle case, below which is fitted a combining tube consisting of several sets of tapering rings joined together by equally spaced ribs. The combining tube is connected to a tail diffuser discharging into a hot well underneath.

The water nozzle case is provided with a nozzle plate containing the water nozzles. The injection water is supplied to the condensers under a pressure of about 10 lbs. per sq. in., corresponding to a 23 ft. head, and discharged through the water nozzles, which are designed to pass a specified amount of water depending upon the conditions of flow determined by the water pressure and the existing vacuum. As the water jets emerge from the nozzles, they are directed into the throat of the combining tube, where they unite to form a single jet. The exhaust steam enters the condenser chamber through the exhaust steam inlet, flows through the annular passages between the tapering rings, comes into direct contact with the converging water jets and is condensed. Because of the combined effect of the external water pressure, the vacuum existing in the condenser, and gravity, the multiple water jets attain a velocity which is sufficient to entrain the condensed steam, air and non-condensable gases, and to discharge them into the hot well against the pressure of the atmosphere. The water jets create the vacuum by condensing the steam, and maintain the vacuum by entraining and removing the air and non-condensable gases.

The energy of the water jets is sufficient to overcome the friction and back pressure in the tail diffuser, wherein the velocity head of the water is converted into a pressure head that is large enough to overcome the atmospheric pressure.

This type of condenser does not depend upon the vacuum produced for its supply of injection water. In most jet condensers, where the injection water is drawn into the condenser by means of

the vacuum created therein, the supply of water decreases with the vacuum at periods when sudden overloads are thrown on the turbine, because the water flow varies directly as the difference between the vacuum in the condenser chamber and that in the suction lift. In other words, when there is the greatest demand for condenser cooling water, the supply available is the least. The low-level multi-jet condenser, however, avoids this difficulty and is therefore adapted for plants where the suction lift of the water is considerable and where the power demand fluctuates, as in electric railway power plants, central light and power plants, etc., etc.

The multi-jet condenser requires a greater water-to-steam ratio per lb. of steam condensed than other low-level types, because the water accomplishes the removal of both water and air from the condenser. Nevertheless the total power to operate the multi-jet compares favorably with the power required by other jet condensers. This is so because the pump supplying the injection water operates under conditions favorable to centrifugal pumps, that is, under a low suction head, and thus the maximum pump efficiency is obtained.

Fig. 3 gives the all-year performance of the two No. 43 multi-jet condensers under three-quarters load and under full load conditions—corresponding to 84,000 and 112,000 lbs. of steam per hr. respectively. As shown by the figure, at no time does the vacuum fall below 28 in., even in summer, when the temperature of the injection water is as high as 78 deg. F.

The accompanying table itemizes the performance test data referred to above. Particular attention is directed to the vacuum obtained, 28.33 in. referred to a 30-in. barometer. This is 0.08-in. above the vacuum 28.25 in. guaranteed by the manufacturer for 70 deg. F. cooling water. During the test the temperature was nearly 1 deg. F. higher, or 71 deg. F.

TEST ON NO. 6 CONDENSERS

Average Load of Unit, K.W.	7450
[illegible] at Throttle, Lbs. Gage	177.9
[illegible] at Throttle, Deg. Fahr.	477.5
[illegible] In. of Mercury	30.04
Vacuum On Condenser, Referred to 30 in. Barometer	28.33
Absolute Pressure In Condenser, In. of Mercury	1.67

CONDENSER 6A.

Injection Water Pressure At Inlet, Lbs. Per Sq. In.	10.4
Injection Water G.P.M. (Calculated From Pressure In Nozzles)	10,312
Injection Water Temperature, Deg. Fahr.	70.7
Temperature Of Water Discharged, Deg. Fahr.	81.4
Temperature Rise of Injection Water, Deg. Fahr.	10.7
Steam Condensed, Lbs. Per. Hr. (Calculated From S=GPM x (T2 - T1). 2	55,169
Water to Steam Ratio	93.5

CONDENSER 6B.

Injection Water Pressure At Inlet, Lbs. Per Sq. In.	10.2
Injection Water G.P.M. (Calculated From Pressure In Nozzles)	10,273
Injection Water Temperature, Deg. Fahr.	71.0
Temperature of Water Discharged, Deg. Fahr.	80.6
Temperature Rise of Injection Water, Deg. Fahr.	9.6
Steam Condensed, Lbs. Per Hr. (Calculated As For 6A)	49,310
Water To Steam Ratio	104
Total Steam Condensed, Lbs. Per Hr. (Calculated From S=GPM x (T2-T1) 2	104,479
Total Steam By Flow Meter, Lbs. Per Hour	111,246
Total Injection Water, G.P.M.	20,585
Water To Steam Ratio Overall	92.5
Water Rate of Turbine, Lbs. Per KWH. (Using Flow Meter Reading)	14.95

Overall water to steam ratio and water rate are figured from flow meter readings.

G.P.M. are calculated from pressure on condenser nozzles.

Vacuum of—28.25 in. should have been obtained based on curve submitted.

Vacuum of—28.33 in. actually obtained.

0.08 in. amount in excess of guarantee.

The evident advantage of the twin condenser arrangement is greater flexibility and greater reliability. It is possible to shut down one unit and to operate with one condenser and one injection pump only during periods of light load or during the cold season. Thus a spare unit is available at all times in case one of the condensers or pumps has to be shut down for overhauling, in an emergency, etc.

The fact that the water is supplied by pumps external to the condensers and that the continuous water supply is entirely independent of the vacuum in the condensers removes the two greatest objections to the ordinary type of low level jet condensers—thereby greatly increasing the reliability of the unit and materially lowering the maintenance costs and the time out of service for repairs.

In the twin arrangement, the tail pipes of both condensers are equipped with gate valves in the discharge. When the gate valve of the idle condenser is closed, the possibility of flooding this condenser is eliminated, and any water that may seep through from the hot well, due to the suction effect of the vacuum, is drained off into the operating condenser by means of an equalizing pipe connecting the two condenser chambers directly above the tail throat. This equalizing line also takes care of any condensation that may collect in the idle condenser.

The vacuum performance of one condenser with full load and three-quarter load, and with various water temperatures is shown in Fig. 4.

NEW HAND TACHOMETER

The hand tachometer illustrated has many distinctive features which will appeal to manufacturers who are endeavoring to increase production. And there are plenty of plants which could benefit by the use of such an instrument, judging from a report recently made public by the Elimination of Waste in Industry Committee of the American Engineering Council, which gave as one of the principal reasons for low production the fact that a large percentage of the manufacturers are operating at approximately 50 per cent efficiency.

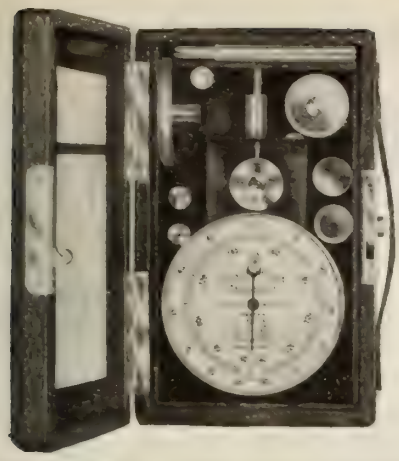
This new tachometer is most compact. It fits the hand conveniently and weighs only 13 ozs. Consequently it should not tire the hand even with long continuous use. Complete with Morocco carrying case and couplings the weight is only 1 lb. 10½ ozs.

It has an exceptionally wide range, being furnished in two standard speed ranges, one 20 to 8,000 and another 40 to 16,000 each with five intermediate ranges which cover every speed met with in industrial practice. This gives approximately 20 inches of effective length to the scale.

Each dial is graduated individually by hand from a master tachometer and covered by a convex glass. Graduations and subdividing lines are engraved on a 3 inch ivory finished dial, making it easy to read.

The oiling system which is patented, provides for three months' supply of lubricant. Felt wicks act as filters, preventing foreign matter from reaching the bearings.

The ball closed opening of reservoir keeps out dust and dirt. The case is also said to be dust-proof, thus pre-



venting foreign matter from entering the inner works and causing wear and deterioration.

This hand tachometer is an addition to the line of Schaffer & Budenberg Mfg. Co., Brooklyn, N. Y., and is marketed under the name of "Columbia."

ARMATURE TESTING DEVICE

An armature testing device has just been placed on the market. It is intended as a production instrument for making simultaneous and instantaneous commercial tests for all electrical defects and their locations in armatures and bare commutator in distinction to the present step by step method which frequently involves hundreds of distinct tests on the same armature. It is claimed that the armeter will indicate whether an armature is o.k. or if not will reveal such defects as: open circuits and where; bad joints (on coarse windings) and where; short circuits between sections and which; short circuited wind-

ings and where;mixed connections and how mixed; irregular number of turns and whether high or low; grounds; tests made at substantial potential, not micro voltages usually used; also instantaneous tests of all sections of a bare commutator for both short circuits and grounds.

Its tests are claimed to be superior tests for it is said to indicate defects that only show up in bad behaviour after running a while. To test an armature its commutator is slipped into the circle of contact fingers in the centre whereupon the circle of small lamps one for each section which are used for indicators will on normal armatures burn as with half voltage, on short circuits light up more or less bright, on open circuits extinguish. Bad joints (on coarse windings) and excess turns are indicated by dimness, other defects by other irregularities. A ground detector operates simultaneously. Lamps are used for indicators as their indications command attention better than eye straining needles. A pilot lamp indicates their correct reading. The entire device is said to be strong and durable and to have no delicate parts aand no moving parts except contact fingers. It is a production instrument not adjustable, but will also indicate shorts in higher voltage winding and open circuits on lower voltage windings at equal speed. It is manufactured by P. E. Chapman, St. Louis, Mo.

MOTOR-DRIVEN FLEXIBLE SHAFT

A motor driven flexible shaft outfit, the motor of which is enclosed in an aluminum casing having a base and handle vertical with it, has recently been placed on the market. A current of air is circulated between the wheel and the armature winding by means of a ventilating fan. The bearings are also cooled by a current of air passing between the scope of the sub-bearing and through a

Motor-driven flexible shaft.

series of holes around the bearings. The flexible portion of the shaft is ¼ in. in diameter, 3 ft. long and wound with wire. The outside covering is of whip cord; 6 ft. of drop cord with an attachment plug are provided with each motor. No external binding post is necessary as the cord is fastened inside the end plate. It is adaptable to all work ordinarily handled by flexible shafts equipment. These tools are being placed on the market by the Hergi Mfg. Co., Bridgeport, Conn.

SELF-OPENING STUD SETTER

A self-opening stud setter known as the Jarvis has recently been placed on the market. The tool is simple in design with all parts hardened, and providing a quick grip and release. These setters are made in three sizes with capacity of the small size up to ½ in. studs, the medium size taking studs up to ⅞ in., and the larger size handling studs up to 1¼ in. diam. Standard shanks are provided with these tools but shanks of special dimensions can be furnished if desired, also special sizes of jaws. These stud setters are being manufactured by the Geometric Tool Co., New Haven, Conn.

INTERESTING WATER WHEEL INSTALLATION

The Pelton Water Wheel Company has issued a 16-page illustrated booklet entitled "The Kern River Number Three Plant of the Southern California Edison Company," written by Ely C. Hutchinson, general manager of the Pelton Company. The hydraulic prime-mover equipment of this plant is particularly notable, since it comprises two 25,000 horsepower Pelton vertical turbines operating under a head of 810-feet, the highest head reaction turbines in the world. In addition, certain special operating requirements called for various novel features in the design of both turbines and accessory apparatus. Copies of the booklet may be obtained from either the San Francisco or the New York office of the company.

BELIEVES CANADA CAN SELL JAPAN GRINDING WHEELS

Writing from Yokohama, Japan, Mr. Malabar, in the office of the Canadian Trade Commissioner said that though the depression existing at the present time in Japan produced many orders being actually put through, investigations have been and are being made into the future possibilities and prospects for business in all the lines which Canada is in a position to export to Japan as favorably as any of her competitors.

"As a result of these investigations," says Mr. Malabar, "a very promising field for Canadian manufacturers opens up in the matter of exporting grinding wheels to Japan. Tentative inquiries made on all sides on this subject have elicited great interest, and several important firms in this country have expressed their desire to be put in touch with a Canadian manufacturer of grinding wheels in a position to export same to Japan, with a view to acquiring the sole agency for such.

"While it is impossible to state just what actual business would be forthcoming as a result of correspondence interchanged between the Canadian manufacturer and the Japanese importer of grinding wheels, still there is a demand, and directly trade conditions brighten it is safe to say that this demand will increase more and more."

Some English and American manufacturers of grinding wheels have obtained a foothold on this market for their products, and it is stated that they are doing well. A Japanese authority on this subject states that there is a considerable demand in this country for grinding wheels of the following specifications:—

Diameter 12 inches, bore 5 inches, thickness 1 inch, grade No. 46, hardness "T."

Diameter 12 inches, bore 1¼ inch, thickness 1¼ inch, grade No. 46, hardness "T" or "M."

Three stores and apartments costing $60,000 will be erected for J. C. Brady, 413 Palmerston Blvd., Toronto.

Management of Direct Current Machinery

By M. BARRY WATSON
Director of Engineering, Toronto Technical Schools.

MOST of the remarks on general care in the foregoing sections of this article apply to alternating current machinery as much as to direct current machines. The chief difference between these machines is that a commutator is made use of in the D. C. generator to rectify the alternating current generated in the armature coils, and in the case of a motor to change the direct current delivered to the machine to alternating current in the armature coils; whereas in the A. C. machines this is not necessary and the leads may be taken directly off from the coils of a stationary armature, or else the alternating current is brought out from a revolving armature by means of slip or collector rings and brushes.

The greatest part of the operating troubles with D. C. machinery is found to be in connection with the commutator, in the form of sparking or burning between the bars of the commutator, or between the commutator and the brushes. Some times burning takes place between slip rings and brushes, and some of the remarks made hereunder apply to collector rings as well as to commutators. The more usual causes of sparking or burning at the commutator will here be listed with such remedies as the operating engineer can apply.

Position of Brushes

The first requisite in regard to brush position is that all brushes or sets of brushes be spaced equal distances apart around the commutator. Before this can be checked up it must be ascertained that all brushes of one holder are in line with the commutator bars. Misalignment may have been caused by a bent brush holders stud, of by the individual holders on one stud being turned at different angles allowing different lengths of the brushes to protrude. If the stud is not straight, it may be taken out and straightened, or if bent near the brush holder ring, it may be shimmed straight by putting bevel washers under the shoulder and the nut on the stud.

The simplest way to see that all brushes are set equal distances apart is to cut a strip of paper the exact length of the circumstances of the commutator, divide it into as many equal parts as there are sets of brushes, raise the brushes and wrap the strip around the commutator. The tips of all brushes should be on the lines marked if they are properly spaced. Slight adjustments can be made by rotating the brush holder stud slightly. Some of the smaller multipolar machines of the "wave wound" type have only two sets of brushes, in such instances, these brusher should be one pole space apart, that is ¼, 1/6 or ⅛ of the total circumference depending on the number of main poles on the machine.

In operating shunt wound generators, it is necessary as the load increases to move the brushes forward (in the direction of rotation) in order to reduce the sparking to a minimum, by compensating for the distortion of the field flux caused by the current in the armature, which increases with the load. The position of least sparking must be found by trial as the load changes.

The brushes of shunt wound motors, on the other hand, must be moved backward with increases of load, and vice versa, in order to prevent excessive sparking. This applies only to medium and large machines, as the relatively small currents carried by little motors do practically no harm when the brushes are permanently set in a good position for average load conditions.

In modern commutating-pole or "interpole" machines the distortion of the magnetic field above referred to is automatically counteracted by the commutating poles, whose coils carry the armature current; thus no change of brush position is required for changes of load. However the correct position of the brushes on such machines should be determined with great accuracy to get the best results. This positioning is generally done by the manufacturer at the factory and marks are put on the frame and the brush holder ring which should coincide when the brushes are in correct position, or in some cases the brushes are mounted in an immovable position so that no mistake can be made in re-assembling or adjusting the machine.

In case the adjustment of the brush position on a commutating-pole machine is disturbed, it can be found by either of two methods. The simplest, but less accurate, is the "mechanical method." On machines where the armature coil width is exactly one pole pitch, the correct brush position is usually in line with the centres of the main poles. This position can be set approximately by sight, but more accurately by tracing the lead from the coil passing directly beneath the centre of the commutating pole to its commutator bar. The brush should be touching this bar. Since this method is not exact, some slight adjustment forward or back may be found necessary after the machine is operating under load to prevent sparking.

The electrical of "kick method" of finding correct brush position is more accurate, but requires the use of a low reading volt meter, say 7½ volts, and an independent voltage supply.

To use the electrical method, first set

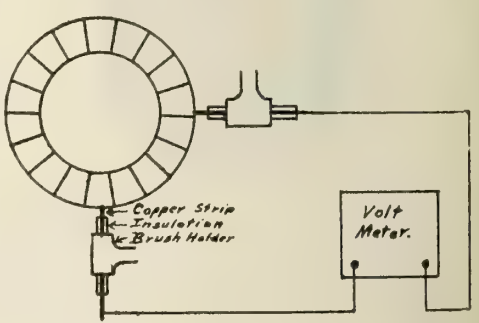


FIG. II

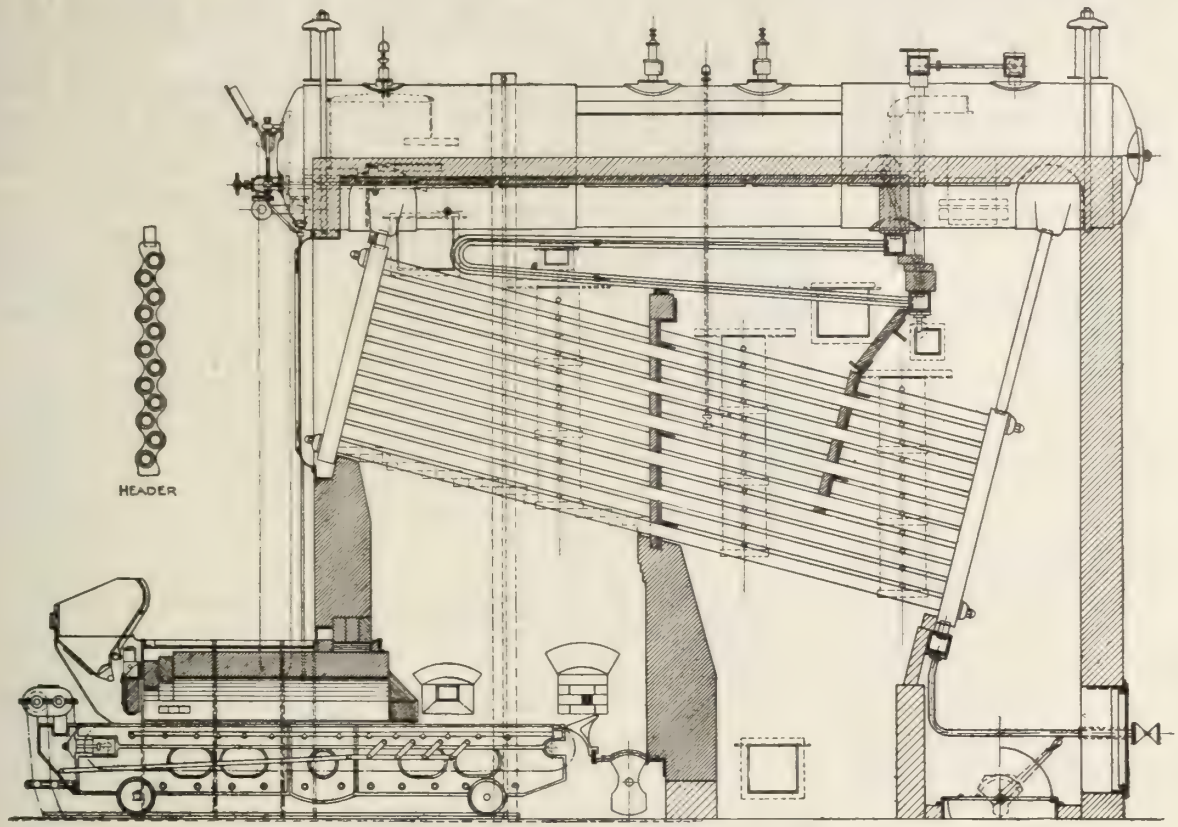
the brushes by the mechanical method, then remove all brushes from the holders, or insulate them from the commutator by sheets of paper. Make two pilot brushes of strips of dry wood or fibre

(Continued on page 38)

BOILER EFFICIENCY



Cut lent by courtesy of Engineering Institute of Canada.

Standard Longitudinal Drum Sectional Header Boiler

The laws of each province provide that every boiler operated within its boundaries must be built to certain recognized standards. All details such as seams, riveting, fittings, etc., must meet the approval of their inspectors before they will pass any boiler as safe to operate.

The Civil Law also states the lowest grade of engineer you can employ and how often he is required to prepare each boiler for inspection.

The lawmakers are concerned with the safety of the public, they do not make it compulsory for you to buy economical plant. You are expected, on your own judgment as a business man, to buy boilers which will give you the highest degree of safety and the greatest return for your money in pounds of water evaporated.

Now just as there are Civil Laws to make sure no unnecessary risks are taken by the public, so there are certain acknowledged engineering laws for the design and construction of economical boilers and furnaces. The success of all such equipment depends upon the success with which these laws, which safeguard your money, are applied—practically.

Boilers made by B. & W. are readily accepted by the authorities, even in the provinces with the stiffest requirements, because they are designed with a higher factor of safety than asked for, and no steam apparatus is made of better material or with more care. Every part is readily accessible inside and out, and with a responsible man in charge to see they are kept clean, there is little possibility of serious trouble.

As regards the efficiency of B. & W. steam plant, we can only ask you here to consider two factors—(1) THE EFFICIENT FURNACE because the fuel is fed evenly and intermixed with a proper amount of air while burning. Perfect combustion is produced and the fuel all gasified in the large combustion chamber before the heating surfaces are reached. (2) THE EFFICIENT HEATING SURFACE because of the proper circulation of the water and hot gases with reference to each other, and because they thoroughly interpenetrate each other, due to the arrangement of the baffles and the manner in which the tubes are staggered.

MANAGEMENT OF DIRECT CURRENT

(Continued from page 36)

that will just fit the brush holders with pieces of copper strip or wire through their centres to make contact with the commutator, connecting these to a voltmeter as shown in Fig. II. Place these pilot brushes in two adjacent brush holders and supply the shunt field coils with about half their normal voltage. If the current is now suddenly broken there will be no movement of the voltmeter if the pilot brushes are exactly right. If no movement is shown the first time this is tried, put the brushes a little out of position so that a movement will be got to make sure the connections through the pilot brushes are alright, then place back to the correct position.

In multipolar machines, this position should be found for each adjacent pair of brush holders, and the final position taken as the average of the positions found. Some manufacturers supply templates with instructions for their use with their larger machines for the proper positioning of brushes.

Other Causes of Sparking

One troublesome cause of sparking is the overlapping of too many commutator bars by each brush, or by one row of brushes. This may be caused by a bent brush holder stud, which may be remedied as explained above; or the cause may be that the brushes in use are too thick or bearing on the commutator at too flat an angle so that the area in contact with the commutator is much wider than the thickness of the brush. The real cause of such sparking of course is that several coils of the armature are short-circuited through the tips of the brushes.

Too low a brush pressure will often cause sparking and burning at the commutator, because the brush does not remain in close contact with the commutator at all times, making either very high contact resistance, or an arc between the commutator and the brush. The usual pressures which will give satisfaction for carbon brushes on a commutator in good condition are as follows: For elevators, cranes, rolling mills, and other stationary motors which are very easily loaded and have frequent stops, 2½ to 5. For railway motors, 4 to 7 pounds per square inch of brush section. For example, assume a generator with brushes ⅝ inch thick and 1¼ inches wide, the area of brush contact is about 1-9/16 square inches, pressure per square inch should be about 2 lbs., or a total of about 3 lbs. per brush. Brush pressure can be measured most conveniently by hooking a spring balance to the holder spring at the point where it makes contact with the brush, and noting the pull when the spring is just raised from the top of the brush.

Too small or too few brushes, heavy overloads or brushes not fitting the curvature of the commutator will always cause a certain amount of burning cause the large currents are forced to go through such a small area. To fit the brushes to the commutator, raise the brushes and pass under them a sheet of fine sand paper, paper side to the commutator and rub it back and forth a few times until the brush tips come to correct shape, taking care that the ends of the paper are not raised above the commutator or the corners and edges of the brushes will bet rounded off too much, defeating the object of the sandpapering.

Brushes may at times get stuck, or may be tight in the holders and in that way fail to make sufficient contact with the commutator causing excessive sparking. Clean out the brush holders with gasoline, if this is not sufficient, see that the inside of the holders are free from burrs or roughness using a fine file. If the brushes are too wide or too thick, they should be rubbed down on a sheet of sand paper, care being taken that they are not made too loose.

Sometimes vibration of the whole machine is responsible for considerable sparking at the commutator. This may be caused by an unsolid foundation, the pound of reciprocating enginees, poor belt lacing or joints, or unbalanced armature. In some cases it may be caused by insufficient flywheel weight when generators are operated in parallel driven by reciprocating engines. The remedies for the above causes are obvious.

Unequal air gaps between pole faces

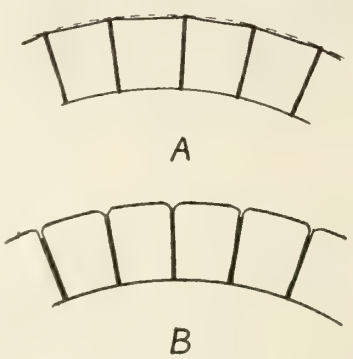

FIG. III

and the armature may cause bad sparking at times. This may be remedied by shimming the poles out, or by rebabbitting or renewing the bearings properly centred.

Poor electrical connection between brushes and holders causes excessive heating and sparking. See that the holders and brushes are thoroughly clean, that the brushes fit the holders accurately and that all connections are tight. Use copper plated brushes and shunts or "Pigtails" properly connected. In using copper-plated brushes on slotted commutators, it is generally necessary to bevel off the edges of the brushes to prevent the copper coating from becoming ragged at the edges of the brushes and causing sparking.

Chattering of the brushes will cause excessive sparking accompanied by noise. This may be the result of the brushes being too loose in the holders, or not sufficient brush pressure. It may be caused by dirty or rough commutator, high mica, high or low bars, flat spots or eccentric commutator.

Broken armature coils usually cause sparking and burning of the corresponding bars. Needless to say this should be repaired as soon as possible to prevent the formation of flat spots on the commutator. The coils can be tested by unsoldering the coil leads from the commutator bars and testing for broken circuit with a magneto, bell and battery or a lamp and normal voltage.

Cleaning and Polishing Commutators

Commutators may be cleaned with sandpaper or gasoline if not out of true. A very fine grade of sandpaper should be used and applied very lightly, preferably by being attached to a block of wood cut to fit the commutator. On unslotted commutators, that is where the mica or insulation between the bars is flush with the surface of the commutator, sandpaper has a tendency to flatten the center of each bar leaving the mica and edges of the bars slightly higher as shown in Figure IIIa. This can be prevented to a certain extent by using a very little oil on the sandpaper, which makes the mica cut easier and reduces the cutting effect on the copper. Very much sandpapering should not be done, or particles of the sand with some of the copper dust will become imbedded between the bars causing partial short circuits and burning. If burning from this cause has been taking place, clean out the space around the burnt spot down to the solid mica and fill the space with Sodium silicate (water glass) or some of the patent commutator compounds on the market.

On a slotted commutator oil should not be used with the sandpaper, as it will cause the copper dust to collect in the spaces between the bars. If used dry the centrifugal force of the revolving commutator tends to throw out any copper dust and sand collected in the slots. On a slotted commutator sandpaper has a tendency to cut more material off the edges than off the centre of the bars giving a rounded surface to the top of the bar and a small area of contact for the brushes causing excessive heating. This is illustrated in Fig. IIIb.

Emery cloth or paper must never be used on a commutator, because emery is an electrical conductor, and if particles become imbedded between the bars, a short circuit and burning is the result.

Hand-Stoning

A very fine grained sand stone may be held by hand flat against the commutator to polish it. This is much superior to sandpapering especially if formed to the curvature of the commutator, because being unflexible, it does not flatten the centres or edgs of the bars. The particles are also more firmly

READ and STUDY the ADVERTISEMENTS

HOW TO FIGURE THE COST OF TIGHT BELTS

By W. F. Schaphorst

In power transmission through belting we have some rather peculiar conditions to contend with. Run the belts tight and the bearings will consume too much power. Slacken the belt and it may slip and we then have the power loss due to belt slip which amounts to one per cent. of the power for each per cent. of slip. With a given belt, then, it may be possible to permit slip to some extent and still save power by running the belt rather loose. But, again, by permitting slip, we are permitting our belts to wear away faster, and the cost of belt renewal may be considerable. It is evident, then, that the ideal condition is to run belts slack if possible, at the same time preventing slip. This condition is possible and is being successfully accomplished by means of proper belt care.

To emphasize the value of running belts properly I have developed a formula which gives the money saved per year by converting a tight, slipping belt drive into a loose, non-slipping drive. This formula includes the cost due to power absorbed by the journals and the power lost through slip. It does not include the cost of belt wear, though, that is a factor that cannot easily be computed mathematically, if at all. Here is the formula:

Cost per year in dollars=

$$\left(\frac{W V^2 (T-t)}{17{,}688\, T\, t} \times \frac{S\, P}{100} C\, N\, D\right)$$

where

W = Weight in pounds of the engine flywheel;

V = Velocity in feet per second of the periphery of the flywheel while running at normal speed;

S = Per cent. of belt slip saved due to belt care and improved methods. For example, if the belt slipped 4 per cent. while running tight and 2 per cent. while running slack, the saving would be (4 minus 2 equals 2) 2 per cent., which should be used in the formula.

P = Horse power of the engine.

C = Cost of power in dollars per horse power hour.

N = Number of working hours per day.

D = Number of working days per year.

T = Time in seconds required for the engine flywheel to come to a dead stop after shutting off steam or gas. The steam or gas should be shut off as quickly as possible. Engine should be driving the belt and pulleys only and driven machinery should be thrown off of the line if possible, in order not to interfere with the test. T, then, is the time required to come to a stop with belt running slack.

t = Time in seconds required for the flywheel to come to rest with belt running tight.

It is evident that T will be greater than t, because with the lessened power consumption of the bearings it will take longer for the stored energy in the flywheel to be consumed. This formula requires at least four tests: First, the belt slip while running tight; second, the stopping time while running tight; third, the belt slip while running slack, and fourth, the stopping time while running slack. Should it be found that there is more slip when running slack than when running tight, the value $\frac{S\, P}{100}$ would be negative, and it may be found that the advantages of slack running are lost. Whatever happens, this formula will tell the truth.

Let us choose a concrete example, where:

W = 3,000 pounds.

V = a mile a minute, = 88 ft. per sec.;

S = 3 per cent;

P = 200 h. p.;

C = $.015;

N = 12;

D = 300;

T = 180 seconds;

t = 150 seconds;

$$\left(\frac{3{,}000 \times 88 \times 88\ (180-150)}{17{,}688 \times 180 \times 150} \times \frac{3 \times 200}{100}\right)$$

$.015 x 12 x 300 = $472.

A saving of four hundred and seventy-two dollars per year should make a test like this well worth the while of any power plant engineer.

MANAGEMENT OF DIRECT CURRENT

(Continued from Page 38)

imbedded in the stone than on the paper and are therefore less likely to wear off and stick to the commutator. Oil is unnecessary in hand-stoning. High mica can be remedied by means of a hand stone, also high bars of flat spots if not of too great extent. It will not however correct eccentricity of the commutator. The machine should be run at normal speed for hand-stoning.

In either sandpapering or hand-stoning great care must be taken not to make diagonal scratches on the commutator. This is especially important in the case of slotted commutators, as non-abrasive brushes are used, and will be worn away rapidly by the slightest roughness instead of polishing out the scratches.

After polishing the commutator the machine should be given a thorough cleaning to see that the copper dust is not sticking to the windings, etc.

(To be continued)

NATIONAL ASSOCIATION OF PRACTICAL REFRIGERATION ENGINEERS THIRTEENTH ANNUAL CONVENTION

The dates for the Thirteenth Annual Convention and Exhibition of the National Association of Practical Refrigerating Engineers have just been announced. This important Convention will be held on November 1, 2, 3 and 4, 1922, at the Planters Hotel in St. Louis, where the entire second floor of that well known hotel, which is one of the largest in St. Louis, has been engaged for exhibition and meeting purposes.

The National Association of Practical Refrigerating Engineers is an Association composed of chief and operating refrigerating engineers, for the purpose of further educating the members of the profession in the art and science of refrigeration engineering.

The National Educational and Examining Board of the Association, after much labor, several months ago commenced to furnish the members with a Lecture Course on the fundamental principles of refrigeration. The Lecture Course is in twenty-two parts and is conceded by many of the best minds in the profession to be the most complete of anything ever written on the subject. This, along with the other educational features offered by the Association, is available only to members.

The cost of joining the Association is so small that every refrigerating engineer should become a member. The initiation fee is only $5, and the dues at the rate of fifty cents a month. For further particulars we are pleased to refer you to Edward H. Fox, Secretary, 5707 West Lake Street, Chicago, Illinois.

Analysis of the gases arising from the fuel bed of a forced draft chain-grate stoker, in tests being conducted at Pittsburgh, Pa., by the Bureau of Mines, show that large quantities of combustible gases rise from the central portion of the grate, while near the back much excess air and little combustible gas are present.

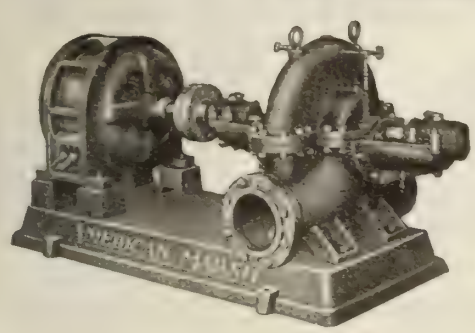
AMERICAN-MARSH PUMPS

Centrifugal and Direct Acting



Designed for use in power plants where absolute reliability and high efficiency are essential. For over thirty-five years American-Marsh Pumps have been recognized as standard throughout the Dominion. There are over 160,000 in successful operation.

The sturdy rugged construction and heavy cast bronze fittings insure long life and a minimum repair expense.

American-Marsh Centrifugal Pumps are built with the same painstaking care that characterizes the construction of the direct acting line.

The line includes:

Boiler Feed Pumps	Jet Condensers
Air Compressors	Vacuum Pumps
Deep Well Engines	Condensation Pumps
Centrifugal Pumps	Sump Pumps

The Importance of the Technical Paper

The technical press has long ago proven itself a fine, progressive proposition, providing a service to industry that is not equalled in any other form of publicity.

To adopt technical paper advertising provides a desirable connection for any manufacturer.

The power plant owner, superintendent, or operator, always consults his technical paper—he reads it thoroughly—or as one subscriber recently wrote:

> *"It is an absolute fact that the engineer is more than ever dependent upon his technical journals for information in connection with new ideas in power plant equipment. He does not depend upon the reading pages SO MUCH AS ON THE ADVERTISEMENT PAGES."*

The argument that the daily newspaper provides adequate "buying power" for the manufacturer of machinery, power plant equipment, etc., is unsound. The "Toronto Globe," in its issue of June 9th, 1922, said: "The newspaper on which hours were spent in less strenuous times, is now 'read' in ten or fifteen minutes at breakfast or after tea." Promote your advertising in the technical papers—papers that the users of your equipment depend upon.

Kingsbury Thrust Bearings
Made in Canada

Our pivoted-block Thrust Bearings are a complete solution of all thrust-bearing problems in hydro-electric units, steam turbines, ships' propeller shafts, centrifugal pumps, and similar work involving heavy loads and high or low speed.
Maximum Durability and Reliability.
Lowest possible Friction.
No limit to loads or speeds.
Protected by numerous Canadian Patents. Complete manufacturing facilities in Canada, insuring prompt deliveries and service.
Send for Catalogue.

Kingsbury Machine Works
Frankford, Philadelphia, Pa.

"Pop Off" Steam Carries Ashes Away

"Into the hole and away they go" describes ash removal with a Green Steam Jet System. At the Kewanee Boiler Co., they use "Pop off" waste steam to do the work.

Write to Dept. X for descriptive literature.

A Striking Message

A STRIKING message to manufacturers of power-house equipment is derived from a letter written by a "Power House" reader in reply to a request for a criticism of the paper and for suggestions as to how it could be improved. Here is the letter:

"I believe Power House compares favorably with other power-house journals in many respects. One department I would like to see at least three times its present size is the selling section. Many of the ads. are from all-American U.S. firms but there must be many others, some of them with Canadian branches and agencies, who do not carry an advertisement in Power House. **This is a mistake on their part,** but for all I know to the contrary it may be due to the lack of energy on the part of the Power House ad. manager in getting after them. **It is an absolute fact that the engineer is more than ever dependent upon his technical journals for information in connection with new ideas in power plant equipment. He does not depend upon the reading pages so much as on the ADVERTISEMENT PAGES."**

Use of Monel Metal for all needle valves in columns and valve discs in gauge cocks—to eliminate steam cutting—is only one of the improvements that help to keep Reliance Safety Water Columns standard in their line.

Does your equipment provide Efficiency ??????????

"POWER HOUSE," edited by Canadians for Canadians conversant with Canadian conditions, is the one logical medium for you to use in order to influence Canadian trade your way. Twice a month Power House will carry your message to power plant owners and operators, fresh every issue; and at a time when THEY ARE OPEN for guidance on matters relating to Power Plant Efficiency in Management, Equipment, and Operation.

ADVERTISE YOUR PRODUCT TO CANADIANS

Our experience proves to us that "Power House," the Power Plant Journal of Canada, is a dominating factor in establishing and maintaining a favorable interest and attitude on the part of the Canada buyer towards efficient power plant equipment.

Say You Saw it Advertised in Power House

POWER HOUSE BUYERS' DIRECTORY

If what you want is not listed here write us, and we will tell you where to get it. Let us suggest that you consult also the advertisers' index facing the inside back cover, after having secured advertisers' names from this directory. The information you desire may be found in the advertising pages. This department is maintained for the benefit and convenience of our readers. The insertion of our advertisers' names under proper headings is gladly undertaken, but does not become part of an advertising contract. Readers are requested to advise the publishers regarding any equipment that they are buying and that is not listed.

Coal Strike

This again brings up the question of Fuel Economy.

Users of **PLIBRICO** Jointless Fire Brick and of our other Fuel Savers can now contemplate a nice reserve effected through use of these lines. This will enable them to meet emergencies and tide over present difficult times. **PLIBRICO** specially suited for Oil Burning Furnaces.

PLIBRICO Bond High Temperature Cements.

528-630 St. Paul St. W., Montreal

One or Many

Which will give the better service—a furnace lining made up of many bricks bonded together, or one of a refractory material that is molded into shape when plastic, forming a one-piece, *jointless* lining?

The latter, most certainly, everywhere known as

PLIBRICO JOINTLESS FURNACE LINING

PLIBRICO is easily applied; it has *no joints* where disintregation may start; it is unaffected by heat up to 3100° F.; it outlasts laid-up fire brick from two to four times; it permits the production of more power at less fuel expense; it lessens labor expense. In a word, PLIBRICO meets the present-day need for a furnace lining that *endures*.

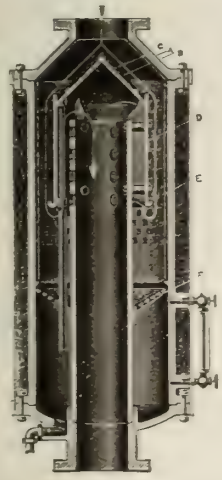
Don't you want to know more about PLIBRICO? Send for our book L-67, on "Modern Furnace Building," and ask to have our nearest representative call.

PLIBRICO is delivered only in steel containers of distinctive appearance as shown below.

DISTRIBUTORS: Beveridge Supply Co., Ltd., Montreal, Que.; **Shell Bar Boico Supply Co., Ltd.**, Toronto, Ont.; **Evans Coleman & Evans**, Vancouver, B. C.; **Winnipeg Supply & Fuel Co.**, Winnipeg, Man.; **Gorman's Ltd.**, Calgary, Alta.

1142 Clay St., Chicago, Ill.

10,000 Sweet's Separators are serving discriminating steam users around the world.



Half of them sold on repeat orders. This record is backed by authentic tests, copies of which are mailed on application. For live steam mains or exhaust lines made in sizes from 25 pounds in weight to 25,000 pounds.

Read our story before buying.

Stop Wasting Oil

The De Laval Oil Purifier returns to service lubricating oil or transformer oil which would otherwise be thrown out. Better still, its continued use constantly maintains the efficiency of such oils.

The De Laval does its work instantaneously, thoroughly and economically by centrifugal force. It is the modern method of making turbines and Diesels give longer and better service, and of prolonging the life of the oil used to lubricate them. It is the far more economical method of maintaining the dielectric strength of transformer oil.

No matter which of these tasks you give a De Laval—you can use the same machine for both—you have absolute assurance that the work is being done better and more economically.

Write for Bulletin No. 105

Williams' "Vulcan" Chain Pipe Vise

UNBREAKABLE, compact, rapid in action and positive in gripping pipe. Attachable **anywhere**—any handy bench, post or other support will serve.

Made entirely of wrought steel; the drop-forged jaws are saw-tempered for file sharpening and the hand-made chains are of the same superior quality as those of our well-known "Vulcan" Chain Pipe Wrenches.

Vises in 3 sizes for ⅛ to 8-inch pipe. Booklet on request.

Continuous Operation of Generators and Motors Insured by Clear, Cool Air

An adequate cool air supply for large electrical generators or motors is imperative. Temperatures of windings must be held within safe limits. Insulation breakdowns must not occur.

The air must be clean in order to prevent accumulation of dust in windings. Dirt reduces conductivity, prevents quick dissipation of heat, makes overheating certain.

"Sirocco" Air Washing Equipment furnishes cool, clean air in just the volume desired and enables you to lower the temperature of generators and motors to a point that insures maximum operating efficiency.

Complete information regarding "Sirocco" Air Washing Equipment for the small power plant or the mammoth central station will be sent you upon request.

Facts and figures regarding "Sirocco" Equipment for your particular requirements will be forwarded you upon receipt of data regarding the electrical equipment that you desire to cool with washed air.

"Sirocco" Air Washers are being used by many power plants for cooling generators and motors.

Reliable Pumping Plant for Lindsay, Ont.

THE De Laval two-stage centrifugal pump shown above is fitted with clutches so that it may be driven either by the Sterling gasoline engine, or by the electric motor, thus insuring practical certainty of operation at all times.

The pump is designed to deliver 1,325 gal. per min. against 290 ft. head, when running at 1,450 r.p.m. Although a comparatively small pump, its efficiency is guaranteed to be 70%.

This is an ideal outfit for municipal supply and fire protection. With engine drive, the speed can be increased to give increased pressure. The pump contains no valves, gears, pistons, or other reciprocating parts, and no packings except two about the shaft. The interior of the pump is accessible for inspection or renewal of wearing parts merely by lifting the casing cover.

De Laval centrifugal pumping units hold the highest records for efficiency.

State your conditions fully, and literature and particulars will be supplied. Ask for Catalog W-103.

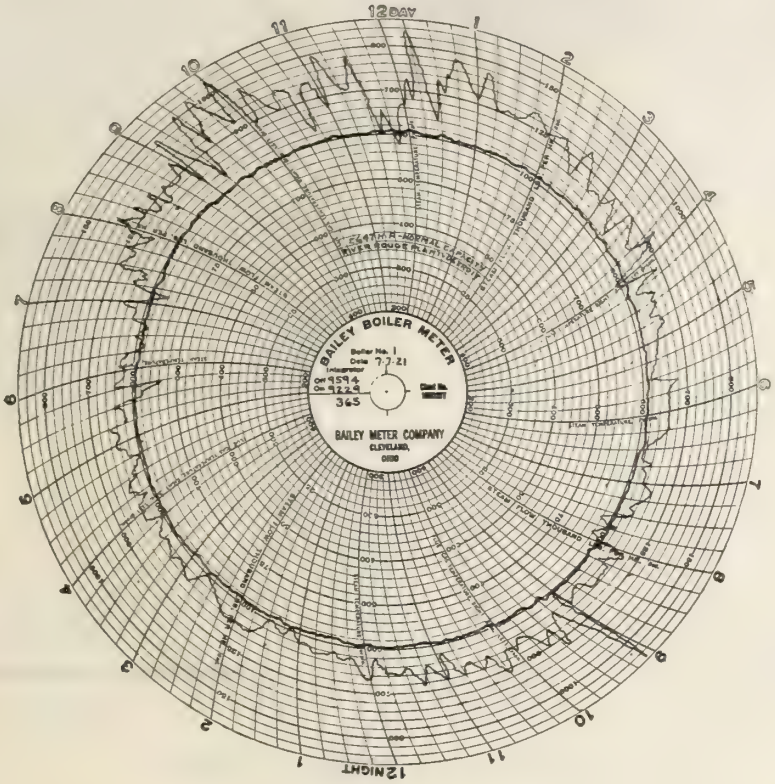
Constant Steam Temperatures Maintained with ELESCO Superheaters at the Ford Motor Company, River Rouge Plant



Maintenance of superheated steam temperatures nearly constant under a wide range of boiler loads, is shown on the above chart taken from one of the 2,647 H.P. boilers at the River Rouge plant of the Ford Motor Company.

The outside irregular line indicates the steam flow, which under normal operation at 100% boiler rating is 82,586 lbs. per hour. It will be seen that this varies from 163,000 lbs. maximum 197.5% rating to 84,000 lbs. minimum 101.6% rating.

The even inside line indicates steam temperatures. At normal pressure (225 lbs. gauge) the approximate temperature of 200 deg. superheat is 600 deg. F. It will be noted that the variation in steam temperature, from 615 deg. maximum to 588 deg. minimum is but 4.5%.

Correctness in design and location of ELESCO Superheaters reduce the variations in steam temperatures to a negligible quantity.

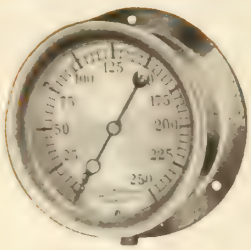
PRESSURE GAUGES



Pressure Gauge

THE Morrison Line of Pressure Gauges and Recording Instruments are the standard for Canada, having been on the market over 50 years.

All Morrison instruments are of the very highest quality and proven reliability and are sold under a full guarantee of satisfaction.

The Morrison Line covers instruments for every purpose — Steam, Water, Air, Ammonia, etc., including:

- **Pressure, Vacuum and Combination Gauges.**
- **Ammonia Gauges.**
- **Locomotive and Duplex Gauges.**
- **Morrison Standard Test Gauges.**
- **Hydraulic, Altitude and Sprinkler Alarm Gauges.**
- **Combination Water Works Gauges.**
- **Pyrometer Gauges.**
- **Engineers' Clocks and Revolution Counters.**
- **Pressure Gauge Testers.**
- **Recording Pressure Gauges.**
- **Blast Pressure Gauges.**

Vacuum Gauge

Diaphragm Gauge

Duplex Gauge

Equalized Altitude Gauge

REPAIRS.

While in many cases it is cheaper to buy new boiler mountings than to have them repaired, this cannot be said of Steam Specialties.

We are fully equipped for handling repairs to gauges and recording instruments, injectors and specialties of every description.

Jenkins Valves

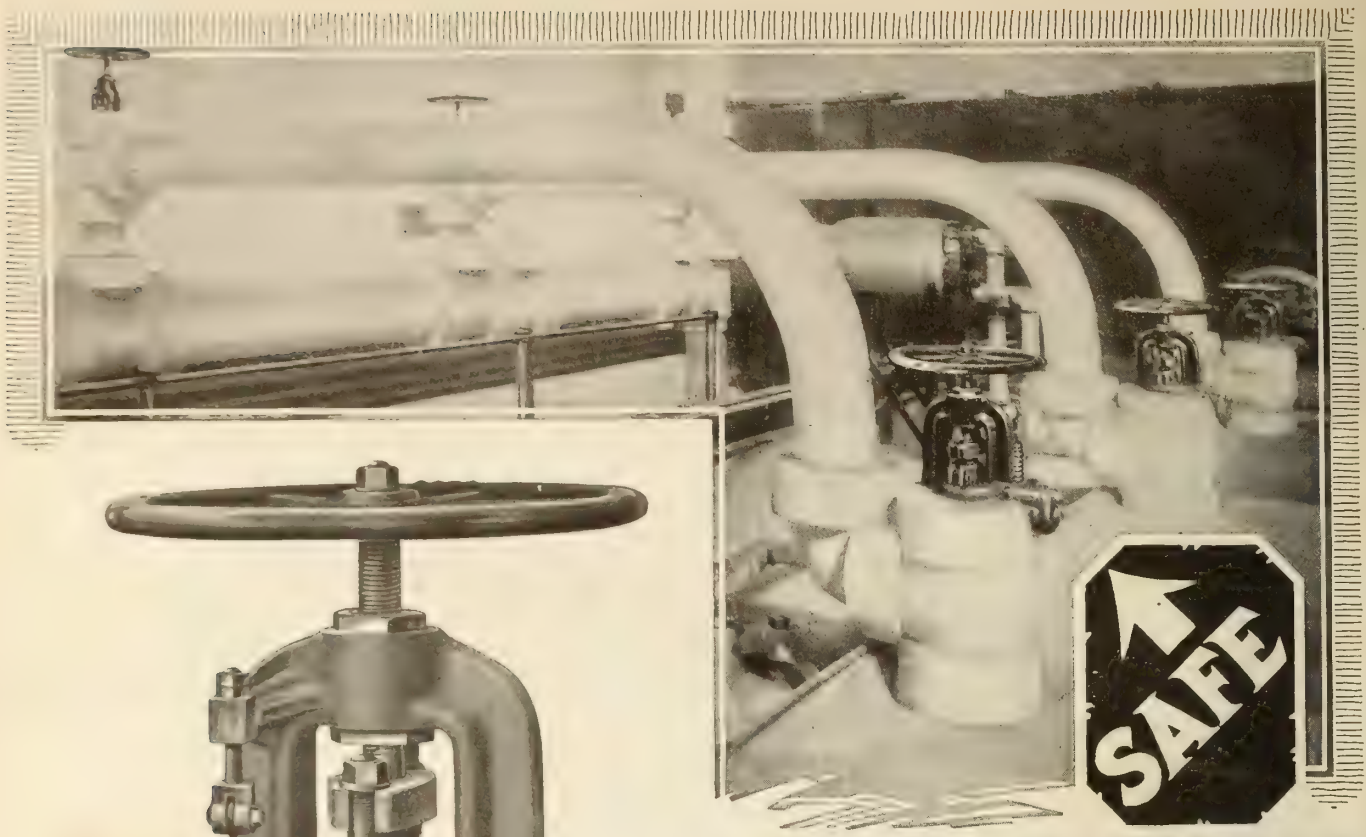
SINCE 1864



LUNKENHEIMER

Safety Non-Return Valves

are safety devices of established merit, providing positive protection to the operatives as well as the plant itself, against the dangers incident to an internal accident to one of the boilers of a battery.

A sudden drop in pressure within the boiler will cause the Lunkenheimer Non-Return Safety Boiler Stop Valve to close instantly and it will not reopen until the pressure within the boiler is raised to that in the header as these valves cannot be opened by hand. They likewise safeguard the lives of workmen who enter a dead boiler. should the regular stop valve fail or be opened through carelessness.

Lunkenheimer construction provides extreme factors of safety,—vital to the severe service these valves perform; minute adjustment to meet individual operating conditions and durability far beyond the average.

Iron Body Bronze Mounted and Cast Steel Monel Mounted for all pressure and temperature conditions.

Files Hand Stokers Getting Results

PANTHER RUBBER COMPANY, LIMITED

GENERAL OFFICES AND FACTORIES
SHERBROOKE, QUE.

SHERBROOKE, CANADA September 23, 1921.

The Waterous Engine Works Co. Ltd.,
Brantford, Ont.

Gentlemen:

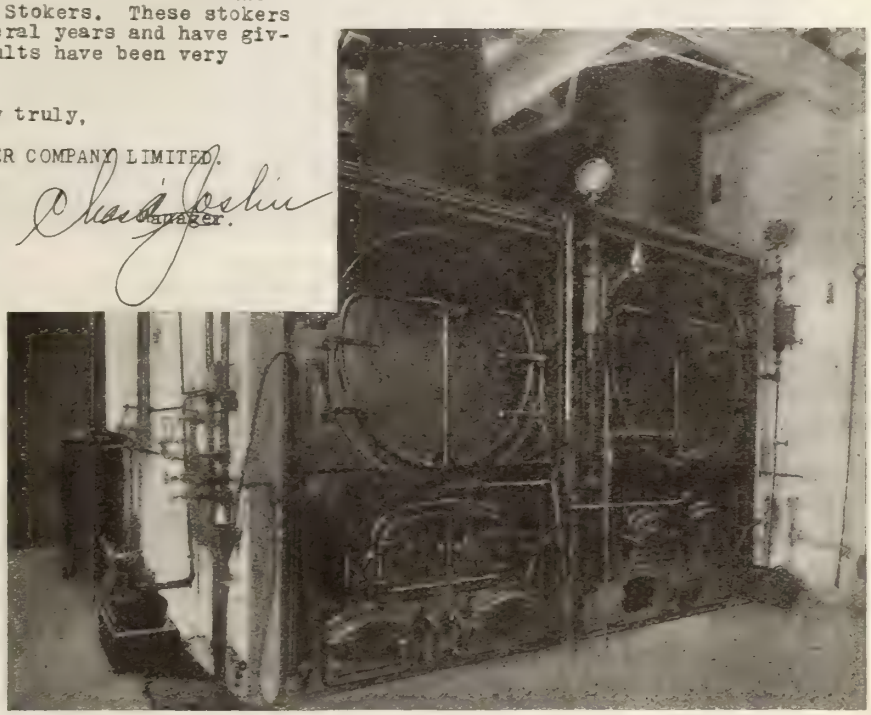
In reply to your letter of the 8th instant we have in our plant the Files Stokers. These stokers have been in operation for several years and have given excellent service. The results have been very satisfactory.

Yours very truly,

PANTHER RUBBER COMPANY LIMITED.

Chas. A. Jodoin
Engineer.

CAJ/RMK



It is the uniform excellent service and general satisfaction that have caused progressive men to select **Files Stokers.** These are typical of the more complete data we have compiled:

One installation (3,600 H.P.) saved enough coal to pay for their stoker investment in five months.

A Files installation operated for five months continuously at an average rating of 223%—doubling their steam output.

Files stokers increased efficiency of one plant sufficiently high to warrant discontinuance of two out of eight boilers.

Here is a ready explanation of these achievements:—

1. **Complete volatilization of green coal, causing intensified combustion and smoke dissemination.**
2. **Correct distribution and proper proportion of air according to load carried.**
3. **Fuel bed continuously kept clean, uniform and rich.**

Given the opportunity we will be glad to present these facts for your complete satisfaction.

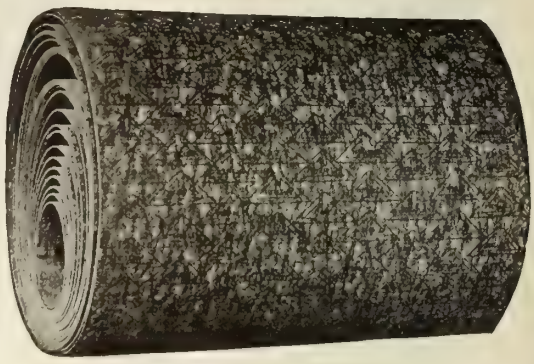
For Tight Joints



Durabla compressed asbestos fibre sheet packing makes tight joints on steam, water, air, oil, ammonia and acids at all temperatures and pressures. Joints can be broken without injury to gaskets. It will not burn out, blow out, pulp at the joints; requires no following up and is not affected by vibration or condensation. Durabla Packing meets all conditions of shipping and storage.

Made in Canada by Canadian Durabla, Limited

and sold on a service basis by

The Canadian Fairbanks-Morse Co., Limited

DURABLA

The M E. reports to the W.M.

It's a real pleasure for the Mechanical Engineer to go over his report with the Works Manager when everything is running like clock-work, due to Imperial Lubrication.

Out-put shows a good increase. Operating costs are lower than ever before. Repair expense and depreciation percentages have fallen off. And most surprising of all is the fact that lubrication costs have actually been reduced

Hundreds of plants, using Imperial Lubricants exclusively, testify to savings up to 35%. It will pay you to call in an Imperial Engineer to prescribe for your plant. Write to 56 Church St., Toronto.

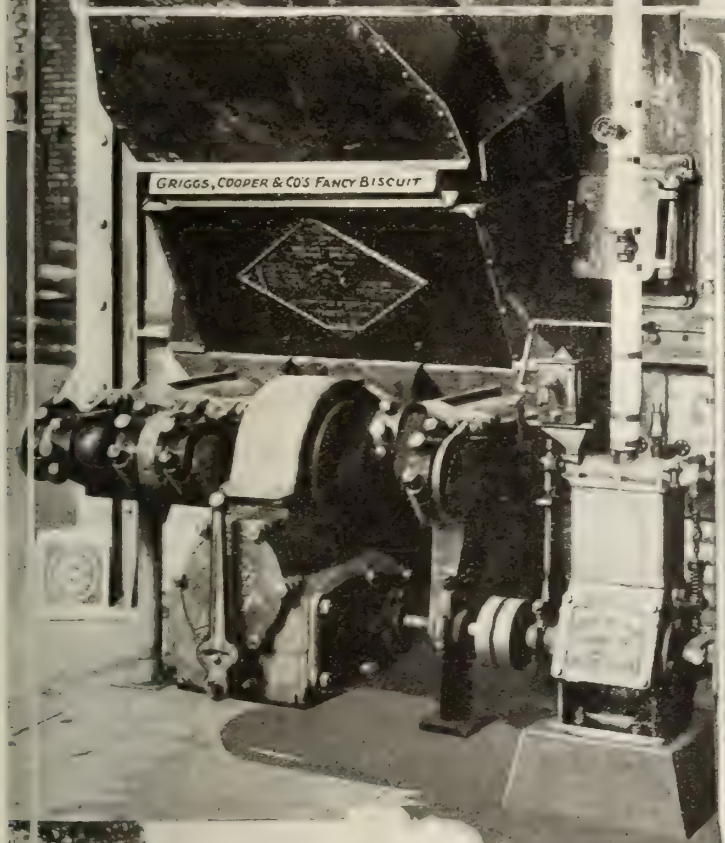
RILEY UNDERFEED STOKERS



Not only in central stations, and large industrial plants, is the RILEY STOKER meeting steam demands, but also in plants using smaller boiler units. Such a case is the installation at Griggs-Cooper & Co., Manufacturing Wholesale Grocers, St. Paul, Minn.

Here a 200 HP boiler is fired by a three (3) retort RILEY UNDERFEED STOKER, the fuel used being Illinois screenings.

When steam is wanted quickly, it can be had easily and economically by increasing the motion of the grates. The whole fuel bed is thrown into action, and in two or three minutes the boilers operate at 200 to 250% of rating. It is this kind of flexibility that relieves you of worry when the load comes on.

Write for our catalog P-7
it gives you all the details.

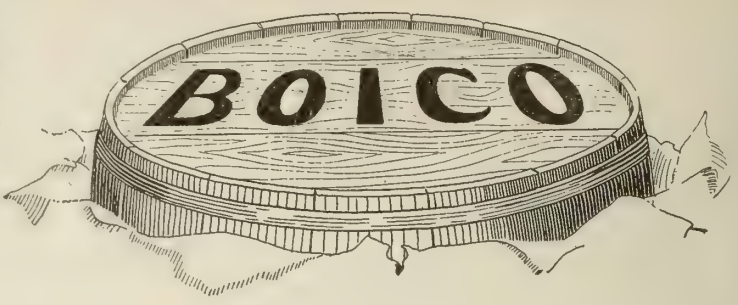
SANFORD RILEY STOKER CO.
WORCESTER, MASS.

The Sanford Riley Stoker Co. is now prepared to equip new Riley Stokers with coal agitators licensed under the Negus-Tiffany patents.

TRADE MARK Rx REGISTERED

The Safe and Certain Boiler Cleanser

PUT a barrel of BOICO in your boiler room. It's the most efficient and economical **clean-boiler insurance** you can adopt. BOICO routs the most stubborn cases of boiler scale formations quickly and thoroughly.



Hundreds of Plants are Using BOICO Every Day With Unqualified Success

What BOICO will do in one plant it will do in another—**it will do in yours.** BOICO loosens and brings away the hardest of old formations and keeps new scale from gathering. Yet it never does the slightest injury to boilers, valves or packings. Neither does it carry over in the steam, nor cause foaming or priming.

We are confident that BOICO will live up to all our claims and are prepared to let you test it FREE of cost. You have nothing to lose by trying it—let us hear from you.

Anti-Clinker Shell Bar Grates

There's no coal waste where these grates are used. Maximum air-space provides for perfect combustion. No clinker formation here, and you get more heat with less fuel.

One-Piece Jointless Furnace Lining

Why shift the blame on your engineer or fireman when it is your furnaces that are not up to the highest point of efficiency? USE PLIBRICO—it lasts longer than fire brick and is easier to instal.

Tip-It Patent Welding Process

With TIP-IT you get tools with shanks of carbon and tips of high-speed steel.

More or Less Boilers?

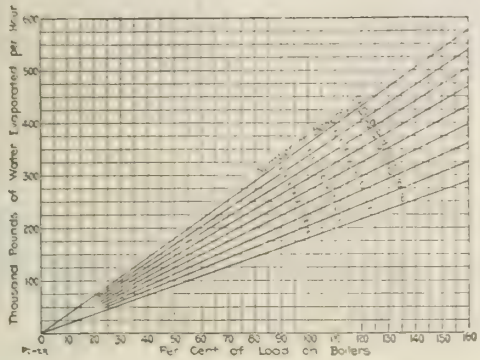

Chart showing number of Boilers to operate.

the horizontal scale is the load in percentage of boiler rating (it having been previously determined at what overload this type of boiler will generate steam with maximum efficiency); the diagonal lines represent the number of boilers in service. The diagram tells immediately whether more or less boilers should be in service for the rate of steaming shown by the Venturi Meter. This is only one of many ways to change the information given by the Venturi Meter into a real money saving which continues as long as the plant is operated.

"VENTURI" Registered Trade Mark

Answers This Question

At this most critical time in American industry, when careful far-sighted management is an absolute requirement for any successful business, why not squeeze every bit of energy from your costly fuel used in the boiler plant? The accompanying cut shows a chart devised by a prominent meat-packing concern, to make certain that enough and only enough boilers are used to take care of the load.

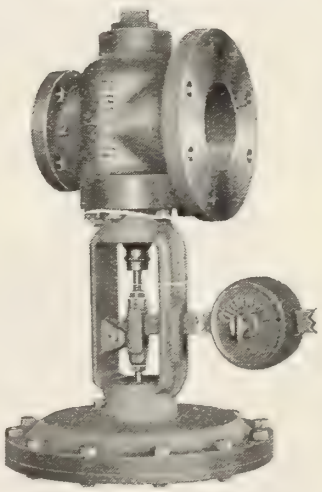
Dunham Reducing Pressure Valve Type 300

The DUNHAM HEATING SERVICE

REG. TRADE-MARK

(MADE IN CANADA)

Accurate Pressure Control



Dunham Reducing Pressure Valve Type 310
(This valve has increased outlet)

Dunham Reducing Pressure Valves will reduce the pressure of steam, air, water, etc., to any desired low pressure and hold it at that point, even though there be considerable variation on the high pressure side of the valve. They reduce in one step, without chattering and are very sensitive in meeting sudden demands. They are applicable to a wide range of initial pressures.

Regulation is by means of a lever and weight which is set at the pressure desired. Each instrument has a double balanced inner valve and seats of special phosphor bronze.

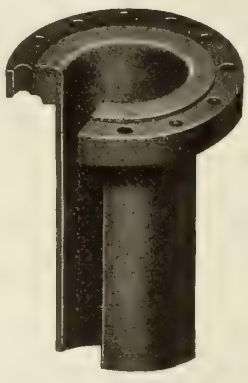
P⊕H FLANGED PIPE JOINTS

SCREWED



P.H. LAP

SCREWED FLANGES.—For general service, our screwed-on flange gives universal satisfaction and is the least expensive. For steam and water lines, at pressures up to 125 lbs., the flange is screwed home and not refaced. For higher pressure, we recommend screwing on the flange until the end of the pipe projects beyond the face, then refacing by taking a cut across the flange and end of pipe, insuring a perfect joint with the gasket bearing on the end of the pipe. This prevents the pressure from working through the thread of the flange, and insures a long life for the joint.

For all High Pressure service, and where it is objectionable to reduce the thickness of the wall of the pipe by threading, we recommend P⊕H Lap Joint.

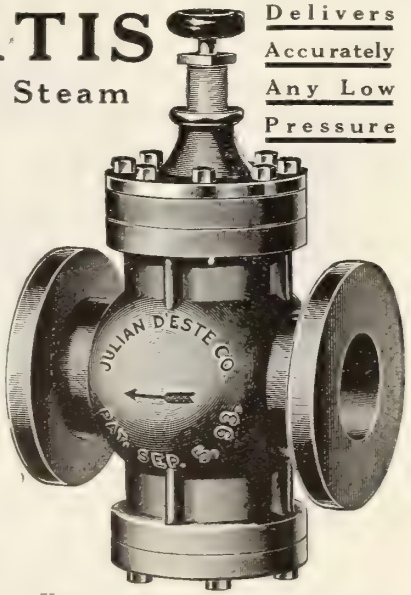
CURTIS
Improved Steam Pressure Regulator

Delivers Accurately Any Low Pressure

A compact, self-contained Regulator suitable for any boiler pressure. It delivers accurately and uniformly any lower pressure from one to within a few pounds of the initial pressure.

It has no levers, weights or projections; no glands or packing; no drip or leak of steam or water. Use it for efficient service on steam-heating apparatus, slashers, jacket kettles, air or water pumps, pulp mills, etc.



The Improved Steam Pressure Regulator is a lock valve, very simple and sensitive. Send for descriptive pamphlet.

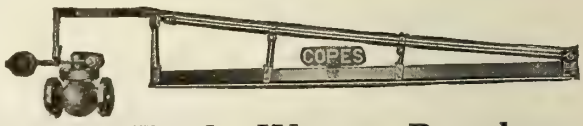
Pressure or Load Changes do not Affect the Accuracy of your COPES



Boiler Feed Water Regulator

A very wide working range is afforded by the simple design of the **COPES** Regulator, which operates on the thermostatic principle.

Not affected by changes in boiler pressure. A high factor of safety adapts the **COPES** to the highest steam pressure used in modern central station practice. Operates efficiently at a working pressure of only 10 lbs.—or more than 300 lbs.

Even if the pressure CHANGES AS MUCH AS 100 LBS., the **COPES** requires no readjustment, but goes on feeding boilers with the same dependability. (Most mechanical feed regulators require readjustment for pressure changes as low as 20 lbs.)

Every COPES is specifically designed for the boiler on which it is to operate. It gives continuous unfailing service, controlling the feed input through the boiler in proportion to the boiler load and furnace conditions. **Automatically, the Copes varies the water level in the boiler, to store excess furnace heat during light loads, and to increase the boiler steam capacity during heavy load demand.**

Our new catalog, just off the press, gives the facts about boiler feed water regulation that you need. Write for Catalog D.

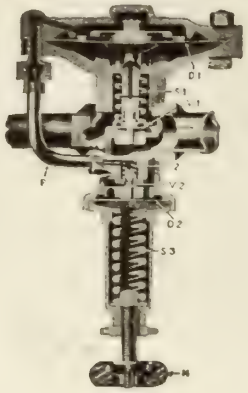
FISHER
TRADE MARK REGISTERED



A PRESSURE REGULATOR That is *Different!*

If you need a valve that will shut off absolutely tight when no steam is required on the low pressure side of your steam lines you should use

FISHER
Pressure Regulator
[Series 90]

It is a pressure regulator, **plus**. It not only serves the desired amount of steam to cooking kettles, rendering vats, vulcanizing tanks and other similar processes, but it also shuts off absolutely all supply of steam when these processes are suspended. This conservation of steam pays for the valve in a very short time.

The Fisher Pressure Regulator is a simple valve—all working parts are easily accessible. Highest grade materials and the Fisher standard of workmanship guarantee a long and satisfactory life to the valve.

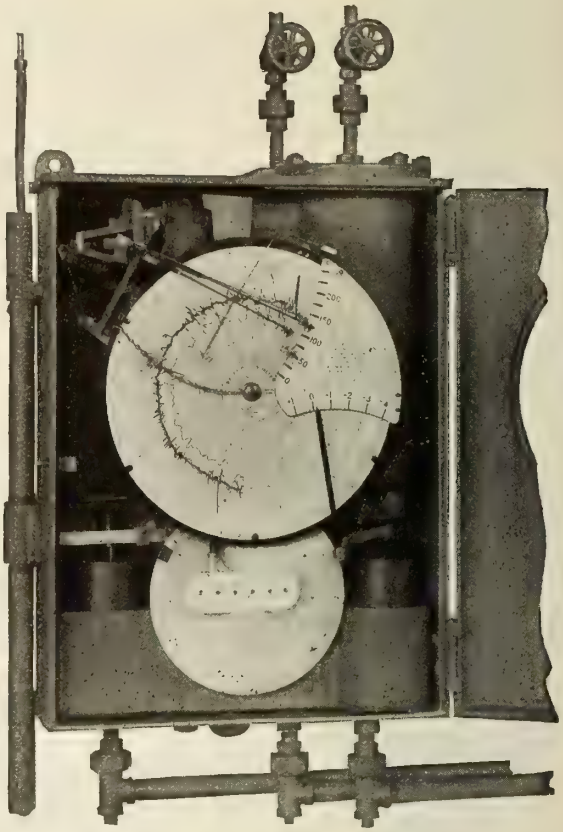
Write for Bulletin 210.
It tells the whole story.

The Fisher Governor Company

935 Fisher Ave., Marshalltown, Iowa

Agencies in all principal cities.

BAILEY
Boiler Meters



IT TAKES a certain amount of air to burn a pound of a given coal. Each pound of such coal when properly burned evaporates so many pounds of water, so that a definite amount of air should be used to generate each pound of steam. Either too much or too little air means inefficiency and causes a lower capacity than otherwise would be the case. Air, therefore, is as much a fuel as coal or oil and a high evaporation per pound of air should be maintained to get the best results.

The Bailey Boiler Meter is a reliable guide for the fireman. It shows him exactly what the operating conditions are at every instant so that he can control the steam output and maintain maximum efficiency. It also furnishes a permanent charted record for future reference and study.

The Question of Accurate Boiler Tests

This Paper Points Out the Unavoidable Innaccuracies Involved in Reports of Boiler Tests, and the Absurdity of Trying to Estimate Values and Quantities to a Decimal Point.

By ALFRED COTTON

Research Engineer Heine Boiler Co. Read Before the A. S. M. E.

A LARGE proportion of boiler-test reports are presented with heat-balance figures carried to one-tenth and even one-hundredth of one per cent. Those who have had much experience in boiler testing know that such apparent accuracy is impossible at present and therefore misleading. In a heat balance recently published the percentage portion does not add to an even hundred. Since the last item is simply the difference between what is known and 100, why not make it agree? The deviation from 100 makes it appear that the items are very precise indeed.

How accurate is it possible to make a boiler test? To determine this, every item entering into it must be considered.

First consider the measurement of the water. If the water is carefully weighed or measured by suitable meters the amount fed may be ascertained well within plus or minus 1 per cent. If meters are used, they may be calibrated before the test, and perhaps afterward as well to insure this accuracy. Proper precautions may be taken to prevent leaks from blow-off cocks, in feedwater heaters, and so forth. Care can also be taken to see that the condition of the water in the gage connections is the same at the end as at the beginning of the test. If this is not done, error may be introduced to the extent of 1 or 2 in. due to the difference in the weight of cold water in the gage connections before blowing off, and of hot water afterward. With an eight-hour test run at rating, the error may be more than 1 per cent. from this cause.

Quality of Steam—Steam Sampling

Then there is the quality of the steam to be accounted for. The entrained water in the sample can be ascertained very closely, but it is sometimes stated with much greater precision than the observations warrant, or than is necessary. A boiler-test report was seen recently wherein the proportion of water in the steam was given to one-ten thousandth of one per cent.!

The temperature of the steam in the expansion chamber of a throttling calorimeter need only be read to the nearest degree; and when averaging the readings, the result need not be expressed beyond one-tenth of a degree. A glance at a steam table will show that the variation is so slight that carrying it further is futile.

But does the sample of steam so examined represent the bulk steam? That is something which is not known, and the more elaborate discussion given in the complete paper seems to show that it is not even nearly representative.

The design and position of the sampling tube are matters of some contention. It is accepted practice to perforate the sampling tube and place it horizontally across the pipe. It is probable that entrained water is commonly in such small particles that it is easily carried in suspension at usual steam velocities. Water flowing along the bottom of the pipe is likely to be mostly condensed steam, and is therefore rightly avoided by placing the sampling pipe horizontally.

The A.S.M.E. sampling tube is made of ½ in. standard pipe and is provided with twenty ⅛-in. holes arranged in "irregular or spiral rows," and usually in a more or less regular helix. It should be inserted in the steam main "at a point where the entrained moisture is likely to be most thoroughly mixed." The word "likely" is highly commendable.

It is most probable that the design of a steam-sampling device should be some what similar to that of a rain gage; and if this is the case, the A.S.M.E. tube is as unsuitable for its purpose as anything which could well be contrived. One of the fundamental requirements in the location of a rain gage is to avoid the proximity of objects which might shelter the instrument or cause eddies. This requirement is ludicrously violated by the downstream holes in this sampling tube. It would appear that the best position for the holes is directly upstream, and that all holes could be used, placing them at least, say, 3 diameters center to center, and making their total area about equal to the twenty ⅛-in. holes or, say 0.25 sq. in.

The most accurate results would be attained with such upstream holes if the velocity of the steam entering the holes approximated that of the bulk flow along the steam pipe. Then the steam and water particles would enter the holes with the least disturbance of their general direction, and consequently the sample would be most representative.

It seems reasonable to think that the actual water present in the steam may be very much less than that observed when we use the A.S.M.E. tube.

If there is much priming, the error in determining the amount on water carried over may approach plus or minus 5 per cent. of that evaporated. But assuming orderly operation and careful observation, the accuracy of the report on water evaporated may be from plus or minus 1.5 to 2 per cent.; but it cannot well be guaranteed to be closer.

Estimating Coal Consumption

The next item to be considered is the coal, and this may easily be weighed well within plus or minus 1 per cent. However, this is but the coal fed to the furnace, and to know the quantity actually burned in relation to the water evaporated, we must be sure that there is the same amount of fuel in the furnace and in the same stage of combustion at the end of the trial as at the start. The only way to find this out is to look at it. Only those who have done this know how impossible it is to accomplish much more than make a careful guess, and it must be done quickly because conditions are changing momentarily. It is not uncommon for different observers to vary in their estimates to the extent of 10 or even 20 lb. of coal per sq. ft. of grate area. In a test during which a total of 250 lb. of coal was burned on each square foot of grate, the error from this source might amount to over 5 per cent. The error will depend on the length of the test, and for 12-hour tests may very reasonably be placed at not less than plus or minus 1 per cent.

Coal Sampling and Analysis

But, unfortunately, this coal weight does not mean anything of itself. We must at least know the weight of dry coal; and if the moisture present in the coal is much over 2 per cent., allowance

should be made for the heat used to evaporate and superheat it. To find out how much moisture there is in the coal, we must have a representative sample, and then we must analyze it for moisture while it is representative. While working down a laboratory sample the coal will either gain or lose moisture. In a warm, drafty room and especially on a warm floor, it will generally lose moisture, perhaps as much as the equivalent of 3 per cent. of the coal or even more. While it is properly bottled up, no further change will occur; but at the laboratory, while being finely ground and while weighing samples, further change will undoubtedly occur and this may be either in increase or reduction of moisture. During all these proces es of sampling from the coal pile to the laboratory drying oven it does not seem possible to certify the moisture closer than plus or minus 1 per cent. and it may easily be put out to plus or minus 2 per cent. Taking the alternative method of drying the coal during the test, there is difficulty of securing a representative sample, for we are now sampling coal which has not been weighed to the firing floor or hoppers; and there is also the further difficulty of crude drying and weighing apparatus. However, this method is likely to be a little more accurate than the orthodox one, and with reasonable care in selecting samples, results may be obtained within plus or minus 1 per cent.

On examining the report of any boiler trial, the first thing looked for is the efficiency at the trial load. Without this, the report does not generally convey information of very much value. To get the efficiency we must know the heating value of the coal; and whether the heating value is found by calculation from the analysis or by the calorimeter, the essential feature is the extent to which the sample is representative. To fully satisfy this requirement it should have come from widely distributed points in the original bulk coal used during the trial. Of course, this condition is very far from being reached even with the orthodox method of quartering down, unless the test is with powdered coal. Still, such a sample is reasonably representative if the work of getting it has been conscientiously done.

Summary of Errors

It is well here to summarize the possible errors and see where they may lead, and this has been done in the following tabulation, keeping them even lower than suggested.

Coal:	Error
Weighing	± 0.5%
Estimating amount of fuel in furnace at start and stop	± 0.5%
Total error of weighed coal	± 1.0%
Variation between original per-percentage of moisture and that in laboratory sample plus failure of sample to truly represent bulk	± 1.0%
Failure of heat-value sample to present bulk	± 0.5%
Total error in analysis	± 1.5%
Total error in B. t.u. in coal (weight and analysis) on which efficiency is based	± 2.5%
Water:	
Weighing or metering, starting and stopping test, gage glass, leaks	± 0.5%
Failure of sample of steam to truly represent bulk steam as to entrained water	± 0.5%
Total error in water evaporated	± 1.0%

B.t.u. in coal burned may vary 97.5 to 102.5 per cent.

Water evaporated may vary from 99.0 to 101.0 per cent.

Reported efficiency may vary from 99.0/102.5 to 101.0/97.5, or 96.6 to 103.6.

Therefore if the efficiency really attained in any boiler trial is 78 per cent., the report may show as low as 75.4 per cent or as high as 80.8 per cent. if all the errors happen to be in one direction. It may be thought that this possible error is placed at a higher figure than occurs in practice; but it must be remembered that generally the errors will be in different directions and to tend to neutralize each other, and it will be seldom that they are all one way. Consequently if a sufficiently large number of trials are made on the same boiler under the same conditions, some of the tests will nearly alway be found to deviate from the average quite as much as the total possible error here suggested.

If the coal and water deductions are relied on, we know the efficiency and the load. But in view of what has been said it is very doubtful if the regular carefully conducted boiler test burning hand or stoker-fired coal can be guaranteed to be closer than within plus or minus 3 per cent.

The Heat Balance

The heat balance is often considered as a final check on the correctness of the test. A boiler-test report without a heat balance is just as good as the other kind as far as efficiency at load is concerned. But the heat balance confers dignity and precision on the test report because all the items add up to 100 and this seems to prove the correctness of everything concerned in it. However, since it does not "balance" or rather that we make it balance, the term "heat balance" is not without humor. If accountants submitted items in their balance sheets called "unaccounted for" amounting to $5 in every hundred dollars there would be considerable unpleasantness. Of course, a heat balance is different because there is the excuse that no way has been discovered to find out the amounts of some of the items and the others are not as accurate as is generally believed. There is a case of four consecutive tests made on the same boiler by an engineering professor of deserved repute and large boiler-testing experience, in which the "unaccounted for" was respectively 8.7, 0.4, 6.4, and 7.4 per cent. The trials run by Dr. Jacobus on the Delray boilers were among the most careful ever made, and the "unaccounted for" item runs from 1.51 to 4.83—a difference of over 3 per cent. Incidentally, the efficiencies in the series of tests vary over plus or minus 1 per cent. from their average rating-efficiency curve.

The real value of a heat balance lie in the presentation of the various losses and their amounts, and therefore it is more a statement than a balance.

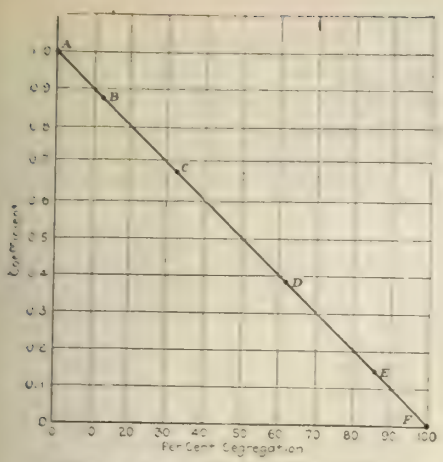
Care has to be taken to get an average sample of flue gas. Its composition sometimes varies greatly across the width of the setting—a much as 5 per cent. of CO_2, according to some experiments, though perhaps some of this variation was caused by the quality of the gases changing rapidly between taking samples. It seems likely that if the gas sample is drawn from some point well within the gas flow, it is fairly representative, for if that were not so, the "unaccounted for" would show a still larger variation that it actually does. This also applies to exit gas temperature, where the radiation effect may affect the readings 50 deg. fahr. With care in placing the instruments the error is perhaps within plus or minus 20 deg. fahr., or about plus or minus 1 in the percentage of heat loss to the stack.

Efficiencies

Even the efficiency as now reported does not provide a proper basis for making trials under different conditions. An efficiency of 75 per cent. with a steam pressure of 225 lbs. is a better performance than the same efficiency at 75 lb. pressure. To be serviceable for comparison, the efficiency should be based on what is theoretically possible in each individual case, and this is governed by the temperature of what is being heated and not by the temperature of the atmosphere.

At first sight it appears that it is not theoretically possible to get the exit gas temperature below that of the boiling point. Therefore the efficiency should be based on perfect combustion with the theoretical amount of air and the products of combustion cooled to the boiling point for the existing pressure. This is not very difficult and the 100 per cent. figure would be set for particular fuel and steam pressure under consideration. The efficiency would be the percentage of the figure attained on the test and might be called the "actual" efficiency to distinguish it from the efficiency as now reported, which might be called the "theoretical" efficiency.

Whether the mean temperature of the water in the boiler or that at the gas exit should be used, is another consideration. In a horizontal water-tube boiler, for instance, the lowest tubes may be 15 ft. below the water level. The added pressure due to this head of water is 6 lb., making a total pressure of 156 lb. when the gage pressure is 150 lb. This increases the boiling point 3 deg., and either the water is hotter at the bottom



Effect of Segregation of Feed Water.

of the boiler or no steam is made there.

The temperature to be used is really dependent upon the extent to which the cold feedwater is segregated. The boiling point may be considered as the proper temperature to use with a boiler in which the feed is so mixed with the circulation that no cold water comes in contact with the heating surface, while with a separate economizer or a flash boiler the temperature of the feedwater should be adopted. But difficulties at once arise with boilers where there is partial segregation. In boilers having integral economizers the feedwater may be wholly or partly segregated. In integral economizers of the Badenhausen type, for instance, there is considerable circulation within the economizer, and the temperature of the water where the gases leave will certainly be well above that of entering water. A somewhat similar condition contains in the rear bank of the Stirling boiler, which is, or used to be, often called the "economizer bank."

It appears, then, that the design of boiler must be taken into consideration and the temperature chosen be that of the boiling point, or of the cold feedwater, or somewhere between these points according to the extent of segregation of the incoming feed. A chart like Fig. 1 could be used and a position on the curve agreed upon for every type of boiler, such as the following:

Pos.	Type of Boiler
A	Horizontal water-tube Scotch marine Horizontal return tubular
B	Stirling with rear circulators
C	Stirling without rear circulators
D	Boilers with integral economizers having free circulation
E	Boilers with integral economizers having restricted circulation
F	Boilers with separate economizers Flash boilers

It is not intended to propose that the positions thus suggested by way of illustration be accepted, either absolutely or relatively. But as an example, with a boiler having 25 per cent. segregation, the coefficient as read from the chart is 0.75. Suppose the boiling point is 370 deg. and the feedwater enters at 130 deg., then the difference is 240 deg., and 0.75 of this is 180 deg. Then 180+130= 310 deg. fahr. which is the temperature to be used.

It might be advisable to make some kind of allowance for the rate of driving, because this would have some effect on the temperature to be used in those boilers having partial segregation of the feedwater.

Probably the simplest way to dispose of the matter is to take the temperature of the water in the boiler at the point where the gases leave, making regular observations during the test. In this way there woud be no contention whatever as to the proper temperature to use. The average of these observations would be recorded in the test report.

The efficiency based on the temperature of the water in the boiler is the only efficiency by which different boiler performances may be intelligently compared. But it must be remembered that the limit of temperature on which it is based is artificially imposed. It may be considerably lowered by the installation of an economizer, and perhaps still more so by apparatus yet to be devised or more generally adopted. When an economizer is added it may be that the efficiency—which will now be based on the feedwater temperature—is lower than before. Of course, this is quite proper because this is really the actual efficiency of the apparatus as a heat generator and absorber. But for the comparison of one steam plant with another or for changes in the circumstances on the same plant such as the addition of the economizer, the efficiency based on the heat value of the coal must be used. Therefore it appears highly necessary that both of these efficiencies be reported in every test. These efficiencies may be stated as:

$$\frac{\text{B. t. u. in steam}}{\text{B. t. u. in dry coal}} = \text{Theoretical Boiler and Furnace Efficiency}$$

$$\frac{\text{B. t. u. in steam}}{\text{B. t. u. available}} = \text{Actual Boiler and Furnace Efficiency.}$$

All comparisons of efficiency are properly based on the load in percentage of the boiler rating. When a superheater forms an integral part of the boiler, the heating surface is greatly increased. The efficiency is greater owing to the increased heating surface reducing the temperature of the escaping gases. But still the efficiency is plotted against boiler heating surface only. This is wrong. The combination should be rated at some higher horsepower than that of the boiler only. It would be a very difficult matter to decide how much to allow for superheating surface as its heat-transfer rate is quite different from that of boiler heating surface. But superheating surface should be rated as the equivalent of so much boiler heating surface.

The same thing applies to economizers. What is the proper way to report a boiler where there is an economizer? I quote from a test report case of unquestionable authority:

Water-heating surface, sq. ft.	4400
Builder's rating, h. p.,	440
Economizer heating surface, sq. ft.	6290
Hp. developed for boiler	1231
Hp. developed for boiler and economizer	1350
Percentage of rating developed for boiler	277
Percentage of rating developed for boiler and economizer	305

What is the meaning of the last item? The one above it is the regular statement of percentage of rating. But the boiler did not develop more horsepower or a higher percentage of rating because there was an economizer near it. The economizer did this extra work—not the boiler. What percentage of the rating of the economizer did the economizer develop?

The steam, or its equivalent when electric motors are used, consumed in driving stokers and mechanical-draft apparatus should always be ascertained and reported as a percentage so that it may easily be deducted from the efficiency by any one suffiicently interested. In testing all or most other apparatus, the efficiency is output divided by input; but in boiler testing we do not know yet how to accurately measure the output. We weigh the water going in and boldly state it as output. Surely the available steam sent away from the boiler is the real output, and if so, all steam used to make the boiler and its accessories work should be allowed for. As conscientious engineers we have always strictly seen to it—and shall continue to do so—that such things as internal-combustion engines, hot air engines and the like shall be tested with a brake so that we know exactly what is their actual output; and the more power they consume in making themselves work, the more for them. But we seem to prefer to avoid telling any one what the real output of a boiler is.

Economizers raise the efficiency by lowering the flue-gas temperature, and they sometimes do this to a point where the gas temperature is too low to produce sufficient chimney draft, in addition to increasing the draft resistance. So an induced-draft fan is used but the power taken to drive it is rarely considered.

The following very imposing array of data is sometimes presented:

Water evaporated, actual, per lb. of coal as fired.

Water evaporated, actual, per lb. of dry coal.

Water evaporated, from and at 212 deg., per lb., of coal as fired.

Water evaporated, from and at 212 deg., per lb., of dry coal.

Water evaporated, from and at 212 deg., per lb. of combustible.

These items are sometimes carried to one-thousand of a pound and none of them mean anything. Any kind of evaporation per pound of coal in any condition is without meaning unless the heating value of the coal is known, and knowing this the efficiency, which is

what is desired, can be easily determined.

In The Engineer (London) of February 25, 1921, H. V. Whittaker suggests basing the evaporation on "standard coal" and he further suggests giving this theoretical coal a value of 12,600 B. t. u. If all tests were reported on the basis of this standard coal we would have a definite standard for the comparison of different performances. But why not go a step further and drop the meaningless evaporation per pound of coal altogether and report the result as B. t. u. in the steam per 100 B. t. u. in the coal? This figure is the efficiency without further ado. There is nothing difficult about it. In calculating the test, the B. t. u. in one pound of liquid is subtracted from the B. t. u. in one pound of steam, superheated or otherwise, and multiplied by the weight of water evaporated. The "factor of evaporation" disappears, and the correction for moisture in the steam is just as easy. The B. t. u. per pound of coal is multiplied by the coal weight and divided into the B. t. u. taken up by the steam. The quotient is readily expressed as B. t. u. in the steam per 100 B. t. u. in the coal. The B. t. u. per hour taken up by the steam is easily converted into the obsolescent "boiler horsepower."

The object of all boiler tests is comparison either with some other test or group of tests or with our general experience, which is the same thing. The report should therefore contain everything which will show the relative arduousness of the conditions under which the test was made, including the variation in loads.

Tolerances

In all manufacturing operations it is realized that nothing can be made absolutely correct. Therefore tolerances are allowed. Whether the suggested plus or minus 3 per cent. for boiler trials considered too large or not, the fact remains that the performance of guarantees is demanded without any tolerance whatever. It is said that if guarantees should carry a tolerance of, say, minus 2 per cent., manufacturers would raise their guarantees by 2 per cent., relying on this margin. If all manufacturers followed this policy they would be on an equal footing and no commercial harm would be done. As matters stand now the prudent manufacturer virtually sets his own tolerance by guaranteeing something less than he knows he can accomplish; while if the proposed tolerance is adopted he can guarantee all he knows he can do, and let the tolerance take care of the testing errors.

There is nothing whatever to be gained by reporting efficiency more closely than the nearest tenth of one per cent. or even the nearest half. Not only is such apparent precision as 1 in 1000 unwarranted by the exigencies of boiler testing; but engineering judgment is quite unable to make use of it. It is mentally impossible to differentiate between the relative values of 79.9 and 80.1 per cent. efficiency and it seems only sensible to call it 80 per cent. Especially is such precision absurd, inasmuch as it is not certain that it was not really 79 or 81 per cent., or even a little further away.

HOW TO SPEND LESS FOR COAL

By W. F. Schaphorst

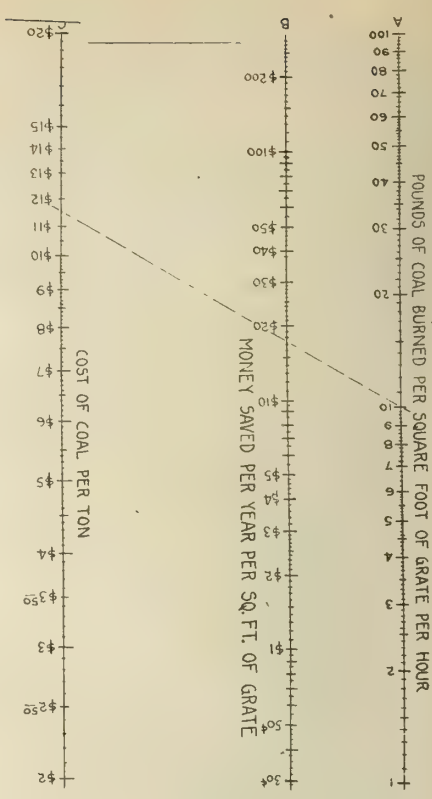
When coal is shoveled into a furnace where does it stop? On the grates of course. Are those grates efficient? Are they designed for the most economical combustion of coal? Are you needlessly burning money on your grates? These questions certainly should not be rudely brushed aside. Grates are worth thinking about because they may be either highly efficient or extravagantly wasteful. That's where you put the coal, in the very first step towards converting it into mechanical energy. That's where it lies through the whole combustion process. We do not take it from the grates and put it somewhere else, as we do other materials in turning out products—it "lives" for a few brief moments on the grate, gives a small part of its life to doing useful work, and also gives a greater share to wastefully heating exhaust steam or atmosphere. After death its remains drop through the grate in the form of ash.

It is therefore plain that the grate has very much to do with the combustion of the coal. That is the place where economy must be effected first of all. I don't know why it is that the grate has practically been ignored by engineers in their efforts for economy in the power plant. It has been pointed out time and again that engineers delight in perfecting engines, turbines, steam lines, condensers, economizers, feed water heaters, and the like, but they keep away from the grate—perhaps because grates are usually so black and dirty. In the process of combustion one can't see any "wheels go round" and mechanical geniuses evidently lose interest.

Every little leak, however, is worth plugging nowadays, and as there are so many big leaks in furnace operation I will dwell on the subject for a moment longer. I have some figures here that should prove of interest.

In a letter from a prominent grate manufacturer he says, "grates will show a saving in fuel of at least 10 per cent. over ordinary plain grates in any case. It has gone as high as 20 per cent. We are willing to guarantee a 10 per cent. saving over plain grates." This statement alone gives us enough data on which to work. What was your coal bill last year? Are you using plain grates? If so, take 10 per cent. of your last year's bill and put most of it in the bank this year by improving conditions. Or, on account of the present high cost of coal perhaps you can "come out even" this year at least.

Getting down to a concrete problem let us say that your plant is a place where coal costs from $11.50 to $14 per ton. Let us assume that you run your



plant 10 hours per day, and 300 working days per year, or 3,000 hours; assume that you burn 10 pounds of coal on your grate per square foot every hour; and lastly assume that the most economical form of grate can be purchased for $5.50 per square foot. How much money would be saved per square foot per year?

There is nothing difficult about the problem. You will readily figure that 3,000 pounds of coal are burned on a square foot per year. If 10 per cent. of this can be saved by installing better grates it is plain that 3,000 pounds of coal would be saved per square foot per year. At $11.50 per ton this amounts to $17.25 per year. That will be the saving at the end of the first year, but it is not the net saving. From it we must subtract $5.50, the cost of the grates, which leaves $11.75 as the saving. Thus you could instal new grates every year and still make good money. If your grate money is 100 square feet you will multiply this by $11.75 to find the total net saving, or $1,175 per year.

To make the computing work still simpler, I have developed the accompanying chart. Simply lay a straightedge across the chart connecting the pounds of coal burned per square foot per hour (column A) with the "cost of coal per ton" (column C) and the intersection with column B immediately gives the saving on expenditures for coal per square foot of grate area per year. From this subtract the price you will have to pay for a square foot of grate and you can decide for yourself whether or not it will pay to make any change. The dotted line on this chart shows how the problem given above would be worked out via the straight-

Overcoming Heavy Costs of Belt Maintenance

Transmission Problems Should Be In Charge of Competent Man —Inspection Should Be Made Regularly—Importance of Proper Alignment—Lacing of Joints Should Be Carefully Performed

By J. H. RODGERS

BELT dressings are of two types: those intended to prevent slippage, and those used to preserve the fibre of the leather. The most common examples of the first class are perhaps soap or powdered rosin, which the average mechanic uses freely. Dressings in this class are often made of some sticky material dissolved in any oily solvent and scented to conceal their odor. Black belt dressings often have tar or asphalt for the sticky material, kerosene or turpentine for the solvent, and oil of mirbane or citronelle for the odorous constituent. Belts treated with such dressings quickly become coated over and soon both belt and pulley are glazed with a dirty surface that slips worse than before. Selecting a dressing for belts is as important as the selecting of lubricating oils for machinery. Some simple test should be used to see that they do not contain any harmful ingredients. In some fluid dressings naptha or gasoline is used. These are initial preservatives of leather and their presence often indicates other harmful ingredients which are kept in liquid form by them. Since volatile oils evaporate rapidly, dressings containing them have to be applied very often to secure any result.

Destructive Practice

When surface dressing—or as it is often called, the "belt stick"—is freely used. it is not uncommon to see pulleys in the condition shown at F, Fig. 6, where large patches of the dressing cling to the face. As said before a belt derives its power from frictional contact with the pulleys and while the pull from a well "dressed" belt may seem better, the general efficiency has not been increased. This may be made more clear when one realizes the air pockets that must be formed between the patches on the pulley surface. To this must be added the pull required when the belt is leaving the pulley. A stamp may be easily placed on an envelope but some action is required in its removal. At your next opportunity notice a drive of this description and listen to the noise when starting or stopping. Just like pulling a porous plaster from your back.

Detection of Naptha or Gasoline

Naptha or gasoline can readily be detected by putting a few drops of the dressing in the palm of the hand and rubbing it until the mixture warms slightly—the odor will be easily noticeable. If the dressing contains oils of a gummy or drying nature, harmful to the belt, they can be detected by putting a few drops on window glass. If after it is left in a dry hot place for a few days, it feels sticky, or if it becomes dry and forms a crust it would be apt to do the same thing on a belt and should not be used.

Another simple test consists in taking a piece of new leather preferably from the belt on which the dressing is to be used, putting a few drops of the dressing on the leather and laying it on the engine cylinder or steam chest until quite warm. Note the time required for the dressing to penetrate the leather. If the surface is left clean and feels sticky, it indicates that harmful ingredients are present. If all of the sample penetrates the leather, leaving no residue, and the spot where the dressing was applied feels soft and velvety, it indicates a good dressing. Common examples of the second type of dressing —intended to preserve the leather—are neatsfoot or Brockton oil, castor oil, and dubbib (a mixture of cod-oil and tallow). These, properly used, will keep leather belts thoroughly pliable, mellow and sufficiently greasy to have the maximum co-efficient of friction. These dressings penetrate the leather and depend for their effectiveness on their action on the leather, while the sticky dressings remain largely on the surface.

The use of sticky dressings often results in pulling the laps apart and peeling off the grain of the leather because of sticking of belt to pulley by the dressing; overstrain of leather due to the use of belts of inadequate size, made to carry overloads by use of such dressings; uneven frictional contact and belt strain due to accumulation of lumps of dressing and dirt on pulleys and belt —actual damage to the leather fibre from components of dressing and from excessive slippage. When a leather belt is slipping badly, because it is not tight enough or because of sudden overload, it may be permissible to use a little sticky dressing. For the continued use of sticky dressings with leather belts there can be no excuse and with the right belt no need. Practically all belt dressings of the second class cause a slight temporary increase of slippage at the time of application—the amount of this depending on the amount of dressing used and on the rapidity with which it is absorbed.

The best time to apply dressing is when the belt is idle and can stand for some time so that the dressing can penetrate into the leather. Penetration is assisted by warming the dressing also. When it is not practicable to apply dressing to the belt while idle, a piece of burlap or waste covered with dressing may be held to each surface of the belt while running and a thin film of dressing be deposited in this way on the leather. The fundamental requirement is to have a clean leather surface to which to apply the dressing. It is worse than useless to put dressing on a belt already covered with dressing, or with dirt or oil. Therefore, remove all excess dirt by means of some form of scraper. A sharp-edged block answers the purpose very well. Then, if necessary, scrub with naptha or kerosene but whether by this or some other method, be sure of a leather surface that you can recognize as leather. Put a little

Fig. 8.—Layout of mule drive. Fig. 9.—Guarding belt from drive gears. Fig. 10. Placing belt on pulley. Fig. 11—Quarter turn drive.

This article was prepared from material supplied by the Saddler and Haworth Co. and the experience of the author. First part appeared in the June 15 issue.

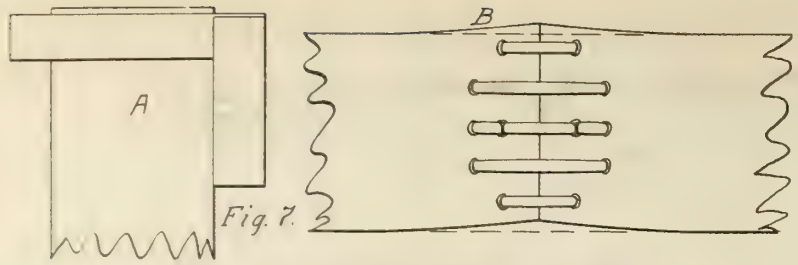

Fig. 7.—A, belts should be cut square. B, result when ends are not cut square

dressing on the driving surface, and more on the surface away from the pulley. A proper dressing will gradually work its way through the leather, and give the driving surface the necessary lubrication, causing it to have that mellow feel, readily recognized by the expert belt man. Probably the best way of doing this is to rub the belt all over with a piece of burlap covered with the dressing, having steadily in mind that too much dressing is apt to be more harmful than too little. No free grease should be apparent on the driving side of the belt after the dressing has been applied.

How To Treat New Belts

Mechanical tests show that the ordinary new belt will not carry the same load as it will after a few weeks service, by from 10 to 20%. It follows that on new belting a good light coat of dressing should be applied in the manner suggested above—before installing. Repetition at frequent intervals for the first few weeks would help, too. Remember that dressing is not put on the belt so that it may stick the belt to the pulley and thus make it pull more. It is put on so that by entering the leather fibres it may toughen them, lubricate them, and thus give longer life to the belt. When ever the leather seems dry, harsh, tinny, does not have the right mellow feel—you may be sure dressing should be used.

Another important factor in belt economy is cleanliness, first of belt and then of pulley. A clean, soft hand will not slip easily even on smooth glass or polished wood. Leather was once skin, and smooth, clean leather will not slip easily on a smooth, bright pulley surface. Belt surface should be clean, smooth, level and comparatively dry. Tests have shown that the coefficient of friction (on iron and steel pulleys) is: .56 when dry, .36 when wet, .23 when greasy, .15 when oily. Therefore it is very important that both belt and pulley be kept as dry and clean as possible.

Too much grease is injurious to leather. Mineral oils in particular rot leather rather rapidly, and where belting is liable to become soaked with oil, mechanical means should be taken to keep the oil from the belt. Where mechanical protection is impossible, the belt should be removed from time to time and the oil extracted with some solvent such as naphtha or carbon tetrachloride.

Packing the belt in dry sawdust or shavings will sometimes answer the purpose. If it is impossible to remove the belt, wiping on the pulleys with a dry cloth or waste will help. Machine oil, in addition to its tendency to rot leather, when present in excess gives a very poor friction surface, as shown in the table preceding. Too much oil will penetrate the belt and affect the adhesive quality of the ordinary cement used in gluing belts together. Frequently, from this or other causes laps start up at the points, a result sometimes due to running belting in the wrong direction.

Direction of Travel

Another point that comes under discussion in connection with leather belts is that of the spliced joints, and their relation to the direction of travel. It is quite evident that the thin edge of the lap may show signs of parting after a period of service. For this reason some men contend that the belt should be run with the splice as shown at B, Fig 1. On this principle the action of the pulley will aid in keeping the thin edge down to its place. On the other hand, some belt men say that the action of the air on the belt surface when in motion tends to lift the edge from its place. As this air action is greatest when the joint is passing around the pulley it would appear that the subject is open to discussion. However, as slow running belts are not subjected to excessive air action it might be said that the method shown at B would be best, and that at A best suited for high speed belts. Irrespective of the advantages claimed for either method, the entire question seems to be one of careful attention in the matter of repairs and maintenance so that faults may be remedied as soon as they are observed.

Avoid Small Pulleys

In double or three ply belts these splices can be run to meet both conditions as shown. In the use of double or triple belts for heavy power drives, care should be taken to use pulleys as large as possible, consistent with speed requirements, as effective heavy drivers are impossible on pulleys of smaller diameter. This is quite clear when we consider the lack of flexibility of the heavier belts. Running over small pulleys also tends to create a fault as shown at G, Fig 1, when the ply of the belt may be loosened.

A condition that sometimes arises in the case of old style lathes is that shown at Fig 9 where the belt will jump the flange and get caught in the gears. A guard will often eliminate this trouble.

Remember that because shafting was in line once it does not necessarily remain so indefinitely, and regular attention to this point will result in a large saving of time, trouble and power. Light machines, especially when not firmly fixed to the floor, are apt to get out of line a little. This misalignment is difficult to detect and always results in uneven belt strain, excessive slip and reduced delivered power.

The Mule Drive

Another drive that is occasionally used is that illustrated in Fig 8. This is known as the mule drive and is adopted where a machine is to be operated at right angles to the line shaft and where a quarter turn drive is not permissible. In the mule drive the connected shafts usually lie in the same horizontal plane, invariably at right angles, where the prolongation of the counter shaft would intersect the main shaft. The intermediate pulleys revolve in a horizontal direction on a vertical shaft. When it is desired to run the belt in either direction it is advisable to have the two main pulleys of the same diameter Collars are necessary on the vertical shaft to support the pulleys. One bad feature in a mule drive where the load is a fluctuating one, is the tendency of the belt to run off the mule on the slack side. It is preferable to have the pull come in the lower side, but in either case the slack side should be provided with a guide pulley C, carried in a bracket B fixed to the mule shaft. This will aid in supporting the belt when the load is on the machine.

Proper Position of Ladder

When placing a belt on the pulleys it should first be located on the "dead" or driven pulley, as shown in Fig. 10, the actual running on of the belt being done on the driving pulley. As the latter is usually on the main shaft, in the majority of cases a ladder is necessary, and in placing the ladder, care should be taken to locate it on the outside of the drive, as shown at A. With the exception of special cases, where the drive shaft is located along a wall, the ladder should never be placed in the position B, and when such is absolutely necessary the shaft should be stopped and the belt run at a very slow starting speed.

When standing on a ladder for this work the body should not be in a strained position, and one hand should be placed on a fixed object for support. For the lighter sizes of belts it is seldom that the speed of the driving shaft is reduced, as the knack is soon acquired of running the belt on. On the heavier belts the work is more difficult, but dexterity is attained with practice. When the belts are very heavy or extra tight, or with a load on the belt, "snapping on" is not so easy, and slipping of the belt is often necessary, while speed is accelerating.

Some Notes On The History of Insulation

The Use of Protective Covering From the Dawn of History to the Present Day is Briefly Outlined in This Article, and the Origin of 85 Per Cent. Magnesia Explained

By T. W. CAVEN

NATURE has given all animals a protective coat against the elements. This coat is of such a nature that it either keeps the heat of the body from being dissipated so rapidly that life cannot be sustained, or such that it keeps the sun's rays from becoming unbearable. Animals living in cold climates are given the most efficient heat insulation found in nature—hair and a thick layer of fat.

In the dawn of civilization man learned that in order to stand the cold it was necessary for him to have some other kind of a protective covering than that which nature had given him. In looking for one, he took that which was nearest and easiest to obtain—the skins of the animals which he had killed.

He first wore the skins of animals as a protection against the elements. The hair was worn on the outside as an ornament in most climates, but in the winter it was worn on the inside, as the aborigine soon found it was much warmer. Of course, the air cells of the hair give the best protection. The more fortunate, or rich—if we may call them such—wore the finest or softest skins since these were warmer. This was due to the greater number of hairs in a given area. Little did the savage think that he was applying the fundamental law of thermal insulation that the greater the number of air cells to a given space, the better the insulation.

Man living in tropical climates seldom clothed himself in furs. He used instead garments of grass or the fibres of plants, to protect himself from the hot rays of the sun.

The first mention of a material used for heat insulation is found in the works of Herodotus. He speaks of seeing brick which floated. They were used by the Romans to put behind marble slabs to keep the heat from being lost by radiation. Some of these bricks have been found in the ruins of the baths of Rome. We now know that they were made of infusorial earth found in the northern part of Africa, where the same kind of material is being mined and used for the same purposes to-day.

A large number of the early writers speak of the use of infusorial earth for the purpose of keeping the heat in chimneys so as to give better draft and to decrease the soot that forms on cold surfaces. In all references they call attention to the fact that brick made of this earth are much lighter than those made of other earth (clay).

Insulation of Steam Engines

James Watt, when he made the discovery that the cylinder of a steam engine should be kept as hot as possible, put wood around the cylinder to keep the heat from being carried off too rapidly This practice was followed up to a very few years ago, as low pressure steam was used and the heat was not high enough to cause the breaking down of the wood.

Count Rumford is given credit of being the first to mention the use of diatomacious silicia as a heat insulating material. He used it about 1790 in the construction of fireless cookers which he had made at the time he was feeding the poor of Bavaria at public soup kitchens. It was due to his discovery that the fireless cooker is so widely used in Europe at the present day.

Authentic data and dates as to the use of heat insulating materials, from this point of time, are rare and of little value. However, with increased pressure of the steam used for power, it became necessary to reduce the loss due to condensation to a point where the loss was not greater than that gained by the higher pressures. Also, since it was necessary to have the steam lines of greater length than had been thought possible in the past, some way had to be found to stop the loss due to condensation in the pipe lines.

The First Scientific Insulation

There is little queston that hair-felt was the first material to be used for insulating heat surfaces. This was due to the fact that wool was the best insulating material then known to man. The use of felt was, in all probability, discovered by some one who had a steam pipe exposed to the weather so that in cold weather the steam condensed to such a point that only water came through. No doubt wrapping the pipe with a piece of wool cloth was tried; and as the condensation was stopped, it was but a short step to a hair-felt covering, since this material was much cheaper than woven cloth.

Felt is an excellent insulating material where low temperatures only are to be taken into consideration, but owing to its poor heat-resisting qualities, it is of no value for temperatures over the point where the material breaks down. It has the lowest conductivity of any of the commercials in use, and is used largely in the insulation of cold storage plants where a flexible material is required.

Cork, flax, wood, and other vegetable materials have been tried but with poor success, because of the low breaking-down point of the material. This causes dry rot or carbonization.

Cork is at present one of the most universally-used materials in the building of cold storage plants. It has low thermal conductivity and light weight, and will resist the action of water better than any of the natural materials. The cost is largely in its favor as its application is easy. The usual method is to use it in large sheets or blocks.

Prejudices Against Insulation

At one time in the last century the advisability of insulating boilers or steam pipes was a question. Writers of that period said that if the surfaces were clothed, the surfaces would rust to such an extent that boilers would be very dangerous; also that the upkeep on steam lines would be greater than the saving. It is hard to believe that less than half a century ago what is known to-day as modern heat insulation was unknown. High pressures of 100 lb. to 300 lb. were thought to be impossible, and superheat was not even considered.

Pipe and pipe boiler coverings there were, of course, Many strange combinations of materials, such as lath and plaster, lasters filled with wool of sheep, plaser filled with slag, straw, cnaff, hair, and vegetable fibres were given in some of the works on the handling of steam plants.

In 1883, Prof. J. M. Ordway, of Boston, made for the Mutual Fire Assurance Companies of Boston, a series of tests as to the origin of a number of fires resulting from "spontaneous" combustion of pipe and boiler coverings. We read in his report a list of coverings which, to say the least, are strange. Here are some of them:

Slagwood in wooden cages covered with burlap or cloth.

Asbestos fibre, then asbestos paper, then hairfelt, then cloth.

Clay, then paper, then hair-felt, then lath and plaster.

Fossil meal, plaster with hair, cloth covering.

Many other combinations are mentioned and some of them are forerunners of some of the best coverings on the market to-day.

Some of Ordway's tests are interesting. He found that "rice chaff moistened with water glass was more efficient than straw rope." When he stated that fibrous or porous matter acts mainly by virtue of its entrapped air," he struck the keynote of modern insulation, but as we find no mention of it anywhere else than in his report, it is hard to believe that he realized the great importance of this statement or that any one else saw anything in it.

Professor Ordway was one of the first to recognize the importance of sectional pipe covering for pipes after they had been installed. He recognized the ease of installation, and, in case of repairs,

the ease with which it could be taken off the pipes without too great a loss when replacing.

In 1884 Professor Ordway stated that "at first sight it may seem as though magnesium is too costly to be taken into account, but there is nothing but the lack of demand to hinder a very economical production of magnesia alba."

Origin of 85 Per Cent. Magnesia

In 1885 H. M. Hanmore, a practical pipe-coverer, began to use magnesia carbonate with his covering materials. He consulted with Dr. R. W. Mattison, who at that time was a large manufacturer of magnesia products. Dr. Mattison saw the possibilities of magnesia as he had been having trouble with his drying room because the magnesia powder settled on the steam pipes and cut off the heat. The doctor was not an engineer, but took advantage of Hanmore's suggestions, and after many experiments, developed what is now known as 85 per cent. magnesia.

It was about this time that the question came up as to whether the covering of boilers and steam pipes was advisable. There were many arguments pro and con, and even as good an authority as Roper was in doubt as to the advantage of it. He states in his handbook, published in 1892, on Clothing Marine Boilers, "Although it must be allowed that in all cases the clothing of marine boilers with non-conducting substances, such as hair-felt, wood, etc., is highly advantageous for the production of steam, yet this practice is alleged in some instances to have induced a rapid wear in the plates of the boilers. This unlooked for result is most apparent in boilers which are frequently used and disused alternately, the corrosion taking place on the interior surface."

It is hard to realize that such theories could have been held at such a late date as the above, but when we consider that even at this time there are a number of engineers who raise the question of damage to the furnace walls in case insulation is used, it is not hard to see why so many years passed before there was any serious effort made to work out the problems of insulation.

Nineteen hundred two saw the first effort to get any basic facts in regard to what insulation meant to the plant operator. That effort was the first ste toward finding what the cost was and what profit could be expected from the investment. It was made by Henry M. Scott, who made tests of what was at that time the largest steam plant in the world, that of the Manhattan Railways Co. His conclusions as to the items to be considered are most interesting and can hardly be improved upon to-day.

They are:

Investment in insulation.

Cost of coal to supply lost heat.

Five per cent. interest on capital invested in boilers and stokers rendered idle through supplying lost heat.

Guaranteed life of covering.

Thickness of covering.

Scott decided on magnesia as being the best at that time. His method of making the test was very interesting, as it was the forerunner of the present method of making tests of insulating materials, did away with the uncertain methods of the past and brought into use methods which deal only with known facts. We will see later what these facts mean and why they are used.

It is too bad that Scott did not give us some report on the state of the art in Europe at that time, as the Germans had gone to the point of bringing out a very efficient insulation in the shape of brick and covering made from kieselguhr. Had Scott made any investigations of this material they would be of great interest at this time.

So much for the general history of insulation in the past. There were many investigators who made a very exhaustive study of the thermal conductivity of materials, but it seems as though they did not take into consideration any commercial or practical value of effecting a saving in fuel. They were interested only from the scientific standpoint.

We can take up any standard work on the transfer of heat and find any number of references made to the work of men as far back as the early part of the 18th Century. It is rather strange, then, that all of the work which had been done on this subject was allowed to lie dormant so long and that it is just now being brought to a point where we are realizing the fruits of all the endeavors.

OVERCOMING HEAVY COSTS

(Continued from page 21)

the most of your belts and to safeguard against the possibility of a sudden shut-down in some department on account of belts going wrong, have all been overhauled periodically. Have greasy belts cleaned up. Have the splices looked over and the laps that have picked up carefully cemented down agan. Have worn out belts cut down to a narrower width and use them over again. In this article we have briefly indicated several ways to keep belting equipment in trim. To summarize: Place a responsible man in complete charge of all transmission equipment; standardize belting as to type, brand, width and weight for every drive; demand regular inspection and reports as to condition of belts; run belting at a uniform tension and as slack as possible; eliminate injurious dressings and use a little good dressing; keep pulleys and belts clean and smooth; make sure that shafts and pulleys and belts are in constant alignment; overhaul belting periodically. If these suggestions are faithfuly adhered to it will mean less power used, less work for mechanics and millwrights, uninterrupted operation of machines, increased output, lower cost of power transmission, and more profits for the firm.

MONO CORPORATION CHANGES

The C. J. Tagliabue Mfg. Co., has taken over from the Mono Corporation of America the manufacturing and selling rights of their entire line of Gas-Analysis Instruments for use in the control of combustion and industrial furnaces.

In addition, Mr. F. D. Harger, general manager of the Mono Corporation of America and associated with Mono interests since 1914, has entered their employ, enabling them to render expert service on all questions of combustion with aprticular reference to Mono installations.

STEAM HEATING

One of the most complete treatises on the subject of steam heating that has ever been published, has been compiled and issued by the general engineering committee of the Warren Webster & Co., N. J.

The information in the book is of a very authoritative nature, having been entirely based on the practical experience of the firm, in their long connection with this industry as manufacturers and installation of steam heating appliances. The book is divided into two parts, the first covering the theory and practice of steam heating in a most complete manner, while the second part is devoted to a detailed description of Webster heating appliances, and their application to various installations. This book should take its place in the literature of the subject as one of the most important contributions yet made. It is published at $3.25 net..

HYDRO ELECTRIC INSTALLATIONS

The citizens of the town of Thessalon have given their consent to a by law authorising the construction of a municipal hydro electric plant, of 200 K. V. A. capacity. There will be 3½ miles of transmission line. A centrifugal, motor driven pump will be installed for water works service, and in addition to this a gasoline engine driven pump will be installed for fire purposes. The plant is expected to be in operation by September 1st.

There have been several newspaper reports to the effect that an American concern have been successful in securing options on the stock of the Canadian Locomotive Co., Kingston, Ont.

Canadian Machinery wrote direct to Wm. Casey, vice-president and general manager of the Canadian Locomotive Works, asking a definite story regarding these reports, and following is his answer:

"With reference to newspaper clippings stating that the Baldwin Locomotive Works is seeking control of this company, I would state that there is nothing true in this information. It is only one of many rumors that have been started by irresponsible parties in Kingston without consulting the officials of the company."

Air Transformer Shows Remarkable Efficiency

New Meaning to the Term "Free Air"—Low Consumption of Compressed Air—Big Saving Effected—Strainer Retains All Dust and Dirt

By D. M. McLEAN, E.I.C.

REMARKABLE savings are being shown by a new device for blowing forge fires and similar purposes recently introduced in Canada. A tiny jet of high pressure air discharges into a bell mouth nozzle leading to the forge and induces a flow of air from the atmosphere into the nozzle where it mingles with the expanding jet and is propelled into the pipe leading to the forge, providing the proper volume of air at a suitable pressure for the purpose.

In present practice, in boiler shops, blacksmith shops, steel erection, ship yards and certain chemical and other processes, it is customary to take compressed air from the general supply line and throttle it down to a pressure of a few ounces before it reaches the forge fire. In rivet heating, for example, the ordinary small portable forge will require about 45 cubic feet of free air per minute to blow the fire. To compress this to the initial pressure of 100 lbs. will take the expenditure of approximately 7½ horespower. In constant daily use, this may mean a yearly cost for air from one forge of at least $300.

With the new blower or air transformer, made by the Ingersoll-Rand, and described below, the consumption of compressed air from the supply line is less than 2 cubic feet of free air per minute, requiring practically one-third of a horespower, because the other 43 cubic feet required for the fire is drawn from the atmosphere. This represents a saving in dollars and cents per year per forge, other conditions being equal, of not less than $275 per forge. The term "free air," therefore, takes on a new and very important meaning.

The chart, Fig. 1, shows graphically the results of three tests of forges operating with and without the blower. The space between the upper and the lower curves indicates the greatly lessened drain upon the compressed air supply, and the consequent savings are expressed in percentages at the top of the cut.

Test No. 1 was taken with a slow fire, No. 2 with a fairly hot fire and No. 3 with an intense fire. These percentages may also be considered as expressing the efficiency of the blower under the varying conditions, and they emphasize unmistakably the futility of the common practice of compressing the required quantity of air to a pressure of 80 to 100 lbs. and then throttling it down for use at a pressure of a few ounces.

These tests were taken with partial needle valve openings and consequent reduced pressure on the jet nozzle. The results of tests with the blower connected to an orifice tank with low pressure nozzle on the outlet to furnish resistance to draft and measure the output are shown in Figs. 3 and 4.

Fig. 2 shows the general arrangement of the device. V is an ordinary needle valve regulating the flow of compressed air. In ordinary operation, one quarter of a turn usually provides sufficient air for the work. After passing through the strainer S which retains all dust and dirt which might clog the device, the air reaches the special nozzle N and is discharged into the bell mouth B which is connected to the forge.

The bell mouth is cast solid with the strainer chamber, and ample space is provided for access of atmosphere air as it is drawn into the bell mouth. The strainer may be easily blown out by removing the plug at the bottom of the chamber. Home-made blowers resembling this device have often been made up from pipe fittings, but cannot attain anything like the results reached by this

Working Pressure on Jet Nozzle lbs. per sq. inch	High Pressure Air Used C.F.F.A. per minute	Low Pressure in Inches of Water	Free Air Delivered C.F.M.	Per Cent. of Air Induced
5	.96	.31	12.15	92
10	1.36	.72	18.5	92.8

100	6.45	5.05	49.0	87

With a 1 in. orifice the New Jersey Blower develops pressure or draft in excess of ordinary requirements for blowing forges. When pressure or resistance against which the Blower delivers is increased, this is at the expense of volume and also reduces the percentage of free air induced. The normal outlet of the Blower is 1¼ inches, giving a greater volume at a little lower draft pressure.

Working Pressure on Jet Nozzle lbs. per sq. inch	High Pressure Air Used C.F.F.A. per minute	Low Pressure in Inches of Water	Free Air Delivered C.F.M.	Per Cent. of Air Induced
5	.96	.29	18.3	94.8

90	5.85	2.95	58.5	90.0
100	6.45	3.25	61.4	89.5

The resistance to flow or draft pressure required in an ordinary forge is somewhat less than for a nozzle of this size. With less resistance the flow is greater in volume. The working pressure on the jet is controlled by the needle valve and can be anything up to the full line pressure. In forge blowing the working pressure required is usually from 15 to 40 pounds and draft pressures of ½ in. to 1 in.

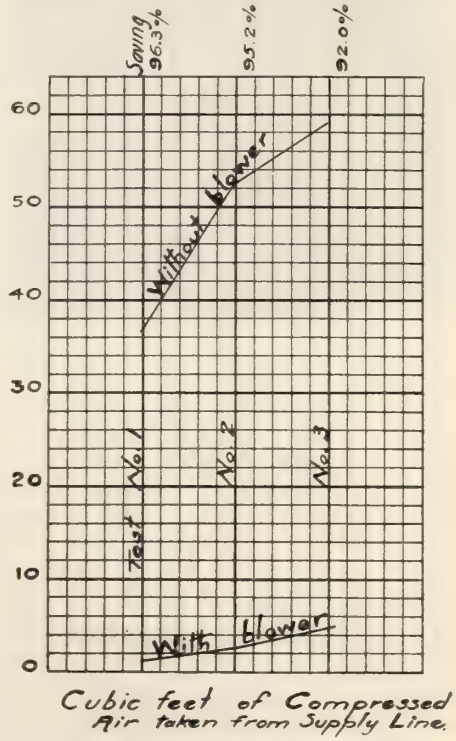

Fig. 1.—Test Shown Graphically

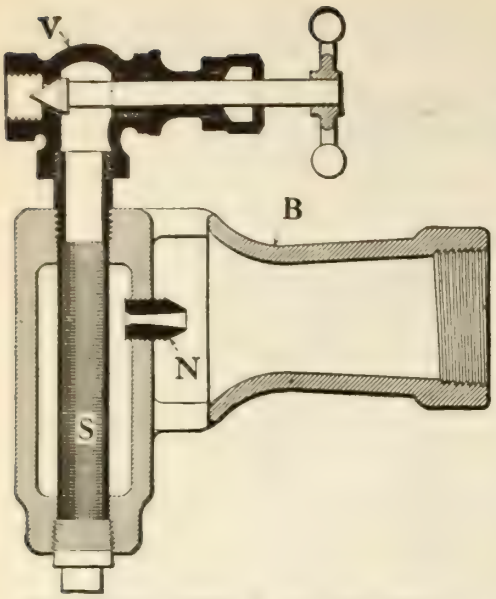

Fig. 2.—Cross section of new forge blower or "Air Transformer," showing arrangement of various parts.

specially designed appliance, proportioned and adjusted for the best possible work. The standard blower of this type is designed to deliver the air at a pressure of 4 inches of water, but higher pressures may be reached by the use of specially designed jet nozzles.

In the tests mentioned above the actual air pressure in the screen chamber

Fig. 5.—Installation of Blower.

below the needle valve was taken. This is the same as the working pressure on the jet nozzle. The cost of this device is such a small fraction of the saving it secures, it may be expected to have quite a wide application in its particular field.

The great value of high speed steel is due to its quality of holding its hardness when cutting at a rate of speed and feed which heats the point of the tools to a red or higher heat, and also the greater length of time the tools will stand up to the work without regrind-

THE ROTASCOPE

The National Physical Laboratory, which was established near London by the British Government, has produced quite a number of scientific instruments of the highest value. One of those was recently shown at a scientific exhibition in London. Its purpose is to render a rotating object continuously visible while it appears to be at rest. The method adopted is different from that of illuminating the object by a series of brief flashes of light. The principle made use of is a property of reflection from a smooth surface which is rotated round an axis parallel to the surface and in line with the axis of the object. When this reflecting surface is rotated at half the speed of the object itself, the image in the reflecting surface appears stationary. This instrument is expected to prove useful for measuring speed and for studying the phenomena of vibration and strain in rotating objects.

HOPES FOR ALCOHOL FUEL

From the scientific point of view alcohol is an excellent fuel for motor cars and other machines driven by internal combustion engines. In view of the importance of the subject, Great Britain has organized careful research not only into the uses of alcohol of different strengths and in different types of engines, but into the possibility of finding some source of alcohol which will be cheap and abundant. This research is being assisted by a Government grant, and it has already produced some highly interesting results. The efficiency of fuel alcohol is in fact higher than that of either petrol or Benzol. A new series of experiments is now in hand with a view to investigating the influence of ether on alcohol and also the influence of alcohol mixed with petrol, benzol, paraffin and other familiar oils. In connection with the fuel question it is interesting to note that discoveries of oil deposits have rewarded the patient investigation which has been carried out for some time in Great Britain. In one part of Scotland oil has been met with at a depth of over 1,800 feet, and the oil is stated to be of excellent quality with a high percentage of petrol, kerosene and lubricating oil.

WHAT IS THE "TRANSVERTER?"

One of the fundamental problems for the electrical engineer is to change alternating current into continuous or direct current. This change has to be made for a variety of reasons; and it is exceptionally important in the case of electric railway working, where many engineers advocate the use of direct current at very high pressure. Two British engineers have been devoting their attention to this matter and have devised a machine which provides far and away the most efficient means of producing high pressure direct current from the alternating current generally produced by steam turbine-driven electric generators. It is impossible to describe this machine without elaborate technicalities, but we may state that the first machine made, which has been under test successfully for about fifteen months, changes alternating into direct current at 100,000 volts with an efficiency of about ninety five per cent. The original design was so excellent that subsequent tests have not led to any material alterations. This machine, which is called a "Transverter" because it first transforms and then converts the current, is expected to be of immense value in the electrification of railways and also in the linking-up of electric power stations which is so necessary to economy in the public supply of electricity. This machine may therefore be regarded as having passed through the experimental stage. Machines with an output of over 700 horse power are expected to be at work in the near future.

CATALOGUES

The Jos. W. Hays Corporation, Michigan City, Ind., have issued a folder describing their "Bestix" cement for boiler settings. The folder contains information on air leaks and their effect.

A book of operating instructions for the Hays Automatic CO_2 and Draft Recorder has been issued by the makers, the Jos. W. Hays Corporation. It shows the construction in complete detail, and gives advice on the packing, setting up, and operating of the instrument. Illustrations of typical installations are also shown. The book should be in the hands of every engineer who has one of these instruments.

A well illustrated, strongly bound booklet describing the Gray System of automatic combustion control has been issued by the Automatic Fuel Saving Co., of Philadelphia and Chicago, represented in Toronto at 71 King St., W. The book describes the apparatus in detail, and with plenty of illustrations. The controller not only regulates the steam pressure by manipulating the chimney damper, but maintains a constant over fire vacuum regardless of the depth of fuel bed, or extent of main damper opening. Thus the over fire vacuum is maintained a constant quantity, while the air necessary for combustion may fluctuate between a maximum and a minimum according to demand.

* * * *

The McAlear Mfg. Co., 1901-7 S. Western Ave., Chicago, Ill., have ready for distribution a new 128 page catalogue, known as No. 27, which illustrates many new devices, including an Individual Temperature Control Valve, Specialties for all Power Plants, Vacuum and Vapor Heating Systems, Oil Refining and Water Works Plants, Plumbing Systems and Marine Service, together with illustrations showing their application and use.

The Individual Temperature Control Valve is self contained and can be applied to any radiator, old or new, without additional piping other than the supply and return.

The Fuel Outlook

THE COAL strike in the United States fields, upon which industrial Canada depends so largely, still continues, without any tangible sign of betterment. There have been several tragic and disgraceful episodes, and these have been passed over with but little comment, or as far as can be seen without any endeavor to punish the ones guilty of aggression. As far as that phase of the strike is concerned, we in Canada have nothing to do with it, it being a purely domestic affair for the United States authorities to deal with or not as they see fit. The whole strike, of course, is a purely domestic affair, but its effects are far from being domestic in their character.

A very large portion of the soft coal which our industries require is imported from the coal fields of the United States, and this is the time of year when in ordinary circumstances, large manufacturing firms try to obtain a sufficient reserve to guard against the delays and difficulties of transportation incidental to winter weather. Owing to the strike, instead of supplies being built up, they are being depleted. Little coal is being mined, and little is being exported, and the immediate prospects for improvement are poor.

It is doubly unfortunate, that just at a time when business in general is taking an upward trend, with every prospect of a continuance in that direction, that the menace of a coal shortage should be looming over us. We have passed through one hard winter, and there is every reason to hope that the employment situation will be considerably better this coming winter than last. It will be too bad if any of the betterment is lost through a shortage of coal.

This is a situation which once more calls to our attention the vast influence which the stationary engineer can exert, by making the most of the fuel that is supplied him. If the average efficiency of the plants in the Dominion was brought up to 60 per cent., instead of the 50 per cent. mark at which it stands at present, there would be an enormous saving in fuel and transportation, the money saved in that way being made available for the further development of industry. If the average efficiency could be brought up to what is now the highest mark achieved in the most up to date plants, which is 75 per cent.. the results would be commensurately greater. This latter figure as an average is one which it is too much to hope for in the immediate future, but there is no reason why the average efficiency could not be raised at least 10 per cent. This is a matter that lies strictly within the power of every man who has charge of a boiler, and it is up to him to do all he can to improve his own standard, thereby improving the general standard.

In the winter of 1917-18 and 1918-19 we saw strenuous, if largely misdirected. efforts on the part of the Government to introduce fuel efficiency in the Dominion, and many thousands of articles and sheets of instructions were printed, on the subject of conservation. Heatless days were instituted, on which factories were compelled to close down, in order to conserve fuel.

The hydro enthusiasts see the solution of the problem in obtaining power and heat exclusively from water power developments, without regard to costs or commercial practicability. In this way they say we can become independent of the U. S. coal supply. The further development of hydro power as carried on under public ownership is something that should be very carefully considered if the people in general are not to be penalised for the benefit of the few.

Until our population increases to a very great extent, so that freight rates can be brought down to a reasonable level, without getting our railways further in the hole, the fuel situation will be such that a large portion of Canada will have to look for its industrial fuel from the United States. The maritime provinces and Quebec can obtain coal from the mines in Nova Scotia by water carriage—the cheapest possible way. British Columbia has her own mines, so that the haul is not so great for her. It is Ontario and the middle western provinces that must depend on imported coal.

The more efficiently the plants are run, the less of this coal will have to be brought in. As we said before, the plant engineers are among the most important factors in the situation.

Who is Responsible?

THOSE WHO are in the habit of girding against what they term "the capitalistic system" would do well to consider some recent remarks of Lord Leverhulme and to ask themselves whether it is not themselves rather than the "system" which is at fault and responsible for the evils they deplore.

"Shall we take the growth and development of a capitalist," he says, "and see how he begins?

"I venture to say, if you will search back during the last two thousand years, you will come to this germ growth of a capitalist. It has been so in all ages; it is so to-day. We will take six young men entering any trade, engineers, or whatever it may be, at the same time, approximately the same age. One of them takes the view of what is outside the wage envelope—he is hard-working and saves. The other five, like the man with the one talent, have no sin; they are simply pleasure-loving, easy-going, and they never think very much about to-morrow. When their money comes it is spent, but they have no sin, no vice—they are merely pleasure-loving, easy-going.

"Now, the young man who saw more outside his wage envelope, saves and prepares a home and marries the girl of his choice. In process of time he is made a foreman; a little later on he is made a manager; a little later on he is an actual employer himself, and further, later on in life, the other five—who have committed no sin, remember—seeing him go past in his motor car, with a smiling wife and bonny children beside him, wonder how it is, and they come to the conclusion that it is the capitalistic system that has placed one man in the motor car and left the other five just where they were when they began. They adjourn to the nearest public house and pass resolutions against the capitalistic system, and determine it must be overthrown immediately, if not sooner."

OUR QUESTION BOX

Questions are invited from readers regarding power plant operation and difficulties encountered

HORSE POWER OF ENGINE

Question:—Will you please inform me through your question box how to find the horse power of an engine, double cylinder, 16 x 20 inches, 225 rev. per minute, cut off at 5-8ths stroke, steam pressure 100 lbs. gauge.

Answer:—The horse power of an engine is dependent on the size of piston, that is, the area, the length of stroke, and the number of revolutions per minute, and the mean effective pressure of the steam. This is stated in a formula as follows:

$$\frac{PLAN2}{33{,}000} = \text{H. P.}$$

In this P is the mean effective pressure per square inch, A is the area of piston in square inches, L is the length of stroke in feet, N is the number of revolutions per minute. The 2 is used to convert the revolutions per minute into strokes per minute there being 2 strokes to each revolution.

The divisor 33,000 is the number of foot lbs. in one horse power. A horse power is a rate of doing work, that is 33,000 foot lbs. in one minute. The power of an engine is measured in horse power as being a convenient unit, and the product of the force, which is the mean effective pressure multiplied by the area of the piston, into the distance through which it acts, that is the strokes per minute multiplied by the length of the stroke in feet, gives foot lbs., which when divided by 33,000, the number of foot lbs. in a horse power, gives the resulting horse power. The mean effective pressure is usually found from an indicator diagram, but when this is not available, and the cut off is known, it can be obtained approximately.

One method is by using the law which states that the pressure and volume of a gas vary inversely. That is, if one pound of a gas occupies a volume of one cubic foot, at a pressure of 25 lbs. per square inch absolute, and it is compressed to one half a cubic foot, the pressure will be doubled. On the other hand if the volume is increased to 2 cubic feet, the pressure is decreased to one half of its original pressure. This is expressed in a formula P V=C or pressure x Volume = Constant.

Now if the cut off in the engine is at 5-8ths stroke, and the gauge pressure is 100, then the absolute pressure is 114.7, or for a case like this we can use 115 lbs. The stroke is divided into eight parts, of which 5 are full of steam when the cut off takes place. That is P is 115 and V is 5 and the product of these is

$$115 \times 5 = 575$$

At the next point on the stroke 6/8ths, the product of pressure and volume must give 575, as P x V= C

$$P \times 6 = 575$$

$$P = \frac{575}{6}$$

At the next point 7/8ths stroke we have

$$P \times 7 = 575$$

$$P = \frac{575}{7} = 82.144$$

while at the terminal or full stroke the pressure will be

$$\frac{575}{8} = 71.875$$

We have now for the eight divisions of the stroke

Pressure	1st division	115
	2nd	115
	3rd	115
	4th	115
	5th	115
	6th	95.5
	7th	82.1
	8th	71.875
		824.475

We divide this by eight to get the mean pressure and this gives us

$$\frac{824.475}{8} = 103.059$$

This however is the absolute mean pressure, and in order to get the mean pressure above the atmosphere we must subtract 15 from the result which gives us 88 lbs. per square inch, mean effective pressure on the piston throughout the stroke.

This is not strictly accurate, as steam does not expand in a cylinder exactly in accordance with the law given here, but it is sufficiently accurate for all practical purposes. In order to get a closer result we should have to use logarithms.

This result again does not allow for any losses, such as the negative work due to cushioning, and a certain amount of loss due to the high terminal pressure keeping the back pressure line high during the first part of the exhaust stroke, the wire drawing of the slide valve ports in opening and closing to steam, etc., so that we can be pretty safe in deducting from the mean pressure as found by the formula 20 per cent. to make up for these losses. This would give a mean effective pressure about 70 lbs. per square inch. We can now put this value in the formula

$$\frac{PxLxAxNx2}{33{,}000} = \text{H.P.}$$

$$\frac{70x20x16x16x.7854x225x2}{12x33{,}000} = \text{H.P.}$$

$$= 315 \text{ H. P.}$$

As there are two cylinders this would give 630 as the total horse power. This seems a high value for an engine of that size, but in the absence of an indicator diagram, it is as close as we can get. The mean effective pressure is the factor that varies the most, and is dependent on cut off, back pressure, cushioning, etc. The revolutions are usually constant in a high speed automatic engine, and the stroke and piston area are always the same.

This leads to a method of easy calculation. Every engineer should have constants for the engine in his charge. For instance in this engine we have a constant speed, constant stroke, and constant piston area. If we multiply these together, and divide them by 33,000, we shall have a number that multiplied by the mean effective pressure at any time will give the horse power. The mean effective pressure of course will vary according to the load.

$$\text{Area x stroke x strokes per minute} = \text{Eng. con.}$$

$$\frac{16x16x.7854x20x450}{33{,}000} = \frac{16x16x.7854x20x450}{12x33{,}000}$$

$$= 4.57$$

Now if the mean effective pressure from the card should be 50 lbs. we have 4.57 x 50 228.5. If it is 60 we have 274.2. If 70 we have 319.9 and so on. If there are several engines in a plant, constants should be obtained for all of them. In some cases the speed may vary, in which case the constant would be the area x stroke, and divided by 33,000 leaving two variables, the pressure and speed.

HOW TO SPEND LESS FOR COAL

(Continued from page 20)

edge. Column B shows the saving to be $17.25. Even if the saving were only 5 per cent. the investment would pay, but inasmuch as 10 per cent. is guaranteed I have based this chart on that figure.

The Operators' Point of View

VOICE FROM THE WEST

Editor, The Power House,

Dear Sir,—

With reference to your editorial and Mr. Wright's letter in the issue of May 20th on "A Move for the Universal Certificate," I have a few observations to make that may be of interest to engineers concerned.

Mr. Wright is to be commended for the practical interest he is taking in the matter, but there are some of us out west here that consider the logical method is not being adopted. In the first place, Mr. Editor, without considering at all the difference in the exams that may or may not exist between the eastern and the western provinces, there is the all-important point of the service qualifications for these exams.

I would suggest that the eastern engineers give Mr. Wright their support towards getting their Provincial Regulations amended regarding the qualifications required for the different grades. Having secured these on somewhat of a par with the western provinces, there would then be common ground upon which to approach the Federal Govt. for the uniform certificate. So long as you have Regulations in the east that permit a man in one province to take a first class exam. with a total steam plant service of one year as fireman, and in another province only one year firing and one year as engineer of a 200 h.p. plant, no system of Identification Cards, permits or anything else will guarantee that man a uniform standing or grading in the west as an engineer.

If a convention of the Chief Boiler Inspectors of the different provinces could meet upon the common ground of equal qualifications and exams for the engineers and their respective provinces it would then be a simple matter for them to draw up and recommend to their governments regulations for the exchange of Provincial certificates upon payment of a small fee to cover registration. The Provincial Boiler Inspectors and Examiners are the logical men to bring this questioin before their respective legislative bodies, because they, more than anybody else, understand the problems connected therewith, and are in touch with both the engineers and governments.

The exchange of Provincial certificates as above, or the Card System advocated by Mr. Wright will never function while the present disparity in the Provincial Regulations exists. While Mr. Wright's card system might work out successfully in the east, let me illustrate its descrepancy when applied to the west. Suppose an engineer to be leaving, say Quebec, to find work in B. C. He would apply for his identification card to the Que. examiner, who would also send a duplicate one to the B. C. examiner which would vouch that the man named was, say a first-class engineer, in Que. To quote Mr. Wright, "when he reaches B. C. he notifies the examiner and produces his card, which upon being compared with the copy in the B. C. examiner's possession, and being found correct, entitles the holder to a permit of the same grade for as long as he wishes to remain in the province."

This engineer having a first in Que. has had to show service of one year as fireman and three years as mechanic to qualify for the exam. there, if my information is correct. But in B. C. this service would only entitle him to try the fourth-class exam. instead of the first and yet under the card system he would expect to be registered as a first-class engineer working under a permit. Before being eligible for the first-class exam. the present regulations would require this engineer to put in the following additional service of three and one-half years:—6 months as engineer of at least a 10 h.p. steam plant, requiring a fourth certificate; 1 year as engineer to have secured his certificate plant, requiring a third; a further year as engineer of at least a 300 h.p. steam plant, requiring a second; and still another year as mechanic. Does Mr. Wright consider this too much steam plant experience to require of a first-class engineer?

On the other hand, suppose an Ont. first-class engineer moved to Alta. and applied for a permit under the card system. So far as the regulations in his home province go, it would be quite possible and not at all improbable for this engineer to have secured his certificate after the following service:—3 years as apprentice blacksmith, 1 year as fireman, 1 year as oiler, 1 year as engineer of a 200 h.p. steam plant, and Ye Gods: 6 years as engineer(?) of a 200 h.p. motor-driven air-compressor plant. Out of 12 years of his experience he could show a total steam plant service of 1 year as fireman, and 1 year as engineer of a 200 h.p. plant. This service being possible in your province, Mr. Editor, can you say it is sufficient to fit a man to take charge of a modern steam plant anywhere in Canada?

The above engineer (?) by means of his identification card would be entitled to trade his experience for registration in Alta. as a first-class engineer, where the local man has to show service under the present regulations of 2 years as machinist or boilermaker, and double the steam plant time required of the Ont. man, and with plants of greater horsepower. Of course the Alta. engineer has not the advantage of the blacksmith apprenticeship.

Considering the above disparity in service required by the present regulations in the east and west, is this not the first kink to be straightened out in the initial steps towards the uniform certificate? If my understanding of Mr. Wright's card system is correct, then if adopted, it would certainly pay the prospective western engineer to go east for his examination (first-class of course), then return and hand in his card for a first-class permit in Alta. and B. C. He would be years ahead.

The point made by both Mr. Wright and yourself, Mr. Editor, that retaining the revenue of the engineers' certificates in the provinces instead of it going to Ottawa "would please the politicians," is a touch of the cultured east that does not appeal to us out here. We are not out to please the politicians. The administration of the Boiler and Engineers' Regulations is kept out of politics in the west, and is in the hands of practical and competent men for the purpose of public safety, not for revenue as a primary consideration. We do not have to renew our certificates yearly here, like getting the car license. When a man pays the examination fee and gets his certificate, why on earth should he be taxed yearly for having proved that he is a competent man to handle steam plants without menace to the public? If your system is right, Mr. Editor, why not expect McGill to attach an annual renewal fee to their diplomas?

There is no desire on the part of the writer to criticize the engineers in the east who have served a real apprenticeship to the craft, studied and earned their certificates; but it can hardly be denied that the regulations there at present require to be tightened up considerably for the good of engineering in general, and before the word "uniform" can be properly applied to the desired Dominion certificate.

The suggestion re the Provincial Boiler Inspectors meeting in convention for the purpose of drawing up re-

gulations for interchange of certificates is made in view of their success with the Uniform Boiler Regulations, and principally because they would know exactly what they were talking about.

Yours truly
J. A. Carruthers.
Lethbridge, Alta.

Editor's Note

We would like to point out to Mr. Carruthers that the very basis of the Inter-Provincial or Dominion Wide certificate is that there shall be both uniform qualifications as well as uniform examinations.

As regards the question of "pleasing the politicians," which Mr. Carruthers mentions, neither Mr. Wright nor the Editor of Power House, suggested that politicans be taken into account in the matter. What was said, had reference to administration and not to politics. Each Government department in every province is dependent on its revenues for operation, and from the point of view of the heads of those departments, giving up a source of revenue is a thing to be avoided. As a general rule the actual administrative head of a department is not a politician in the sense that Mr. Carruthers would infer.

We must respectfully decline to accept the insinuation that the system of renewal licenses is ours in any shape or form. If Mr. Carruthers would read over this correspondence from its inception, he would discover that we are not at all in favor of the annual renewal fee.

We, personally, do not wish to see any distinction between the East and West. The thing to strive for is the thing that will be best for all Canadians, and the Dominion of Canada as a whole. Mr. Carruthers' suggestion for the Chief Boiler Inspectors, or the Chiefs of the Examining Boards as the case may be, to get together and formulate an uniform law, is quite in line with what the writer and I think also Mr. Wright had in mind.

It is very good of Mr. Carruthers to allude to us as the cultured east, and in order to justify his good opinion, we refrain from the obvious retort.

C. A. S. E. EDUCATIONAL PROGRAMME

Eighteen meetings will be held between September, 1922, and May, 1923, under the auspices of the educational committee, Canadian Association Stationary Engineers. Two sessions will be held each month. The list of subjects follow:

(1922) C. A. S. E. (1923)
Educational — Program — Subjects, etc.

1. Sept.—Fuels; wood, coal, oil, refuse.
2. Sept.—Discussion, questions and answers.
1. Oct.—Boilers, furnaces and settings.
2. Oct.—Discussion, questions and answers.
1. Nov.—Combustion, temp. and draft.
2. Nov.—Discussion, questions and answers.
1. Dec.—Grate-bars, shaking and stokers.
2. Dec.—Discussion, questions and answers.
1. Jan.—Appliances, necessary, in a B-R.
2. Jan.—F. W. and Circ. pumps, types and makes.
1. Feb.—Miscellaneous auxiliaries desirable.
2. Feb.—Steam engines, types and makes.
1. Mar.—Meters, indicating and recording.
2. Mar.—Instruments, indicating and recordig.
1. Apr.—Boiler room efficiencies.
2. Apr.—Engine room efficiencies.
1. May.—Report forms and records; also surveys.
2. May.—Useful formula and data, for engineers.

Branch Educational Committee to be appointed by president of the local branch and same is to consist of chairman, who may be an Associate M.; secretary, preferably the conductor, inquisitor or Instructor.

Regulations and suggestions for the program:—

1st. That all papers should be presented by some member of the local branch or association.

2nd. That the questions should originate from members of the branch or association; except such as may be suggested by the general committee.

3rd. That answer may be given by others than members of the branch by permission or request of the chairman of the Educational Committee.

4th. The recording secretary or the conductor is to make brief verbatim reports of the questions and answers.

5th. Credits will be given for the number of questions asked as well as the number of correct answers made; however duplication should be avoided.

6th. Any member having a problem at his plant if marked "urgent" must have priority over the regular program, as he may have to leave before meeting has been concluded.

7th. All questions not marked urgent are to be deferred by the inquisitor until the subject to which they particularly appertain is under consideration, when full credit will be given.

8th. Members should, as far as possible, try to anticipate the questions, or information they desire to have brought out by the discussion, and hand same in writing to the chairman of the Educational Committee (in advance when possible) marking the subject and date for discussion.

9th. Magazines, text books, hand books, etc., may be consulted prior to the meeting for purposes of preparing paper or answering questions; but should not be used during, or subsequent to the meeting, for the purpose of answering questions asked during the previous meeting.

10th. The chairman, secretary and inquisitor, or instructor, should all three sign the written report of the paper read and the record of the discussion consisting of questions and answers; stating specifically "brief verbatim report."

Note.—If prizes are offered to the general educational committee to be awarded to the branch showing highest proficiency, the nature of same will not be disclosed by the committee until contest has been closed.

Geo. J. Soucy, chairman of general Educational Committee, T. H. Fenner, C. E. Hansen.

TORONTO NO. 1 C. A. S. E.

C. A. S. E. Toronto No. 1 are enjoying very prosperous times as is evident by the fact that at the recent C. A. S. E. convention held in Kitchener, Toronto No. 1 were the first prize winners for having the largest increase of new members of all the branches of the C. A. S. E. for 1921-22.

Also in the matters of education the older members helped the new ones to carry off the first prize in the Engineers, educational contest, the list of questions being supplied by a committee selected by The Dominion Flowmeter Co., the judges of the contest being T. H. Fenner, Editor of The Power House, J. Thompson of The Dearborn Chemical Co. and Gordon Keith of "Canadian Manufacturer." This contest was keenly contended by all the Branches of the C. A. S. E. Toronto No. 1 has a very excellent Engineers' Library, two steam engine indicators, a Flowmeter and several engineering instruments and appliances for the use of the members.

The Toronto Executive extends a hearty welcome to all engineers who wish to become members and to all members to help boost the membership of the next convention will be held in Toronto, 1923.

A PERFECT HAND DRILL

The ordinary small hand-operated drill is widely used on account of its convenience, but it has the drawback that it is not quite so accurate in its work as a proper machine drill. With the object of getting over this disability a British firm of tool makers has designed a new type of hand drill which does as good work as the high grade machine drill, while retaining all the simplicity of the hand-drill. Both a high and a low speed are provided; and another very useful feature is the automatic action by which the drill is fed forward as it proceeds through the work. The work table of this little machine can be swung to any angle and also rotated round a vertical column, so that the drilling of holes at any angle is a comparatively easy matter. The machine is designed for hard work and can drill holes up to one inch in diameter. The height of the machine is only forty inches and it is made throughout with exactly the same minute care as is expended on the best British machine tools.

Practical Electricity for the Power Plant Engineer

By G. R. ARCHDEACON, A.M.I.E.E.

THE PASTED plate is much cheaper to manufacture, but has a shorter life than the Plante plate. As the Pasted plate is more in demand we will only consider that type in detail.

In making the Positive plate, certain quantities of Red Lead are mixed with dilute Sulphuric Acid to form a fairly stiff paste. This paste is then rubbed into the skeleton leaden framework, untill this framework is entirely filled with the Red Lead.

About 5 other chemicals are used in combination with the Red Lead with the object of making the paste or active material, more porous, give greater adhesion to the grid. These processes are all closely guarded trade secrets. However fully 90 per cent of the Negative active material is Litharge.

After these plates have been pasted they are kept in a certain temperature for about 10 days whilst they are perfectly dried. They are then taken and placed in large tanks and are "pickled" or formed for about 5 days and then they are ready to be assembled into a cell.

When they are assembled and inserted into the jars dilute sulphuric acid is poured in until the tops of the plates are just covered with this fluid.

This fluid is called the electrolyte. The electrolyte must be made from sulphur. It is most important the electrolyte should be kept chemically pure, therefore acid made from pyrites should never be used, as it is likely to contain injurious substances.

Acid of "full strength" must never be used or the cell will be ruined. The strength must be reduced by the addition of distilled water. Never use water that has not been distilled.

In mixing the acid and the water, never pour the water into the acid. Always pour the acid into the water, or serious accidents may result.

The density of the acid must be reduced from its "full strength" of 1.843 down to 1.220 or 1.280 depending upon the service to which the storage battery is intended.

This is usually determined by the aid of a hydrometer. Water being considered as our standard of density is considered at 1.000. Therefore the weight of our electrolyte is in the ratio of 1280 is to 1.000.

Between the plates are inserted the wooden separators. These separators have to be carefully chosen, and then need to be neutralized by boiling in strong caustic soda, until all the wood acids, or resins are neutralized, and the fibre of the wood rendered porous to permit the free circulation of the electrolyte through the wood.

There are always an uneven number of plates in a cell, and they are so arranged that there is one more negative plate than positive. This is because it is necessary to have a plate surface of opposite polarity facing a plate for it to become active. Therefore the two end plates which face the walls of the jar cannot have that side of the plate active. Therefore that surface is wasted. Fig. 1.

The negative is somewhat cheaper to manufacture than the positive therefore a negative is always used for the end plates, and frequently these end negatives are made much thinnner than the plates used in the interior of the cell.

The glass jars are covered with thin sheets of glass to prevent the electrolyte "spraying over" when no charge.

The glass containing jar should be mounted on double glass insulators. These insulators being immersed in oil, the object being to prevent "creeping" and consequent loss of charge due to the leakage.

We now have the following chemical combinations to consider:

Positive plate. Lead peroxide or Pb O^2.

Negative plate. Litharge or lead monoxide Pb O.

Electrolyte. Sulphuric acid. $H_2 SO_4$.

When the charging current is sent into this combination the process of electrolysis takes place, the hydrogen ions and the oxygen make their passage through the electrolyte acting and reacting upon each other, decomposing the electrolyte, and the chemicals in the plates of the battery.

How The Storage Battery "Works"

In the last chapter it was shown what materials entered into the operation of the storage battery. They are sulphuric acid, water, pure lead, lead sulphate, and lead peroxide.

It is important to notice that all these substances are chemical compounds, with the exception of the pure lead, which is an element.

Sulphuric acid chemical formula H_2SO_4.

This is a chemical compound consisting of 2 parts of hydrogen 1 part of sulphur, and 4 parts of oxygen.

Water—Chemical formula H_2O.

Pure lead—Chemical formula Pb. this is an element and not a compound.

Sulphur—Chemical formula S, this is a solid and an element.

Hydrogen—Chemical formula H, this is a gas.

Oxygen—Chemical formula O, this is a gas.

Lead sulphate—Chemical formula Pb SO_4. This is a solid and is due to the chemical action which takes place immediately lead comes into contact with sulphuric acid.

Lead peroxide—Chemical formula Pb O_2. This is a solid and consists of 1 part lead and 2 parts of oxygen.

It will now be recalled that according to the laws of electroylsis, that when a current of D. C. electricity is passed through any conducting solution, that solution is split up into its original elements.

When the storage battery is connected to a source of D. C. electricity, and a current passed through the solution called the "electrolyte," chemical changes immediately take place, the compounds above enumerated are split up into the substances from which they are made.

We then have lead, or Pb, Hydrogen or H, Oxygen or O, and Sulphur or S.

The sulphur does not completely separate itself and form its original element in a solid form, but its combina-

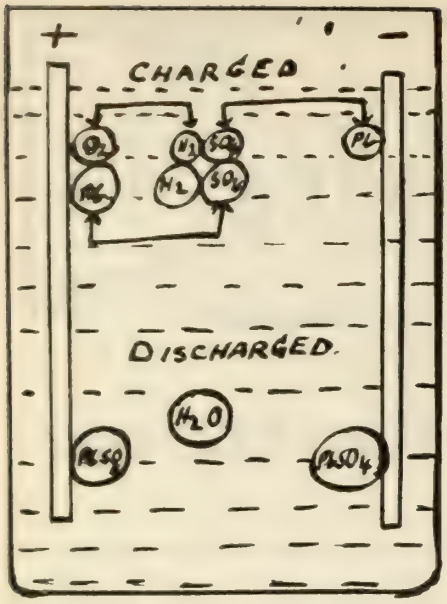

FIG. I

tion with the hydrogen to form sulphuric acid, is split up into H_2 and into SO_4. Whilst its combination with the lead or Pb to form lead sulphate or Pb. SO_4 is split up into Pb and SO_4 respectively.

In other words the sulphur always remains combined with four parts of oxygen.

Let us now consider a simple storage cell having 2 plates only, 1 negative, and 1 positive.

Immediately we pour into this cell the electrolyte, which is a diluted sulphuric acid, the acid immediately atatcks the lead plates, and also the paste or active material on the plates, and begins to turn them into lead sulphate, or what is popularly termed "sulphates" them. If this condition is permitted to prevail for any prolonged period of time, the plates will be ruined. We must arrange to "charge" the cell as quickly as possible after the acid has once been poured into the cell. Let us therefore first consider the fully-charged cell.

When the cell is fully charged, it is in a condition to supply current for a definite period of time.

The positive plate consists of lead peroxide (Pb. O_2).

The negative plate consists of lead (Pb) but in a very finely divided condition, and known as sponge lead.

The electrolyte consists of sulphuric acid. (H_2SO_4) Fig. 1.

When the positive and negative of the cell are connected to some current consuming device, and the switch closed the cell begins to discharge, and the following changes take place:

Positive plate:

Lead peroxide (PbO_2) and sulphuric Acid (H_2SO_4) and two parts of hydrogen (H_2) produces two parts of water ($2H_2O$) and one part of lead sulphate ($PbSO_4$).

This is usually expressed as follows: $Pb\,O_2 + H_2SO + H_2 = PbSO_4 = 2H_2O$.

At the Negative Plate, however, an entirely different set of conditions prevails.

Remembering that the Negative plate is in a fine state of Sponge Lead, the Sulphuric Acid naturally has greater access to the molecules of Lead, and consequently can react upon them to a much greater degree.

These changes are therefore as follows:

Lead (Sponge) or Pb and Sulphate (SO) produce Lead Sulphate. PbSO.

This is usually expressed as follows:

$$Pb + SO^4 = PbSO_4$$

In other words the Chemical changes during DISCHARGE produce Water and Lead Sulphate at the Positive Plate.

Whilst at the Negative Plate only Lead Sulphate is formed.

Chemical Changes on Charging

When we connect the Positive and Negative Plate to a D. C. Dynamo and send Current through the cell a complete reversal of the above changes take place.

The Lead Sulphate which has formed on the Positive Plate is gradually changed back to Lead Peroxide, and the Sulphuric Acid that had impregnated the plate will return into the Electrolyte.

The Lead Sulphate on the Negative Plate is returned to the Electrolyte leaving the plate again pure Lead, only in a Sponge condition.

From this brief explanation it will be apparant that we are not STORING Electricity, the sell is not a STORAGE BATTERY in the popularly accepted understanding of the term.

All the above changes in the Chemical structure of the "working parts" is precisely in full accord with the underlying principals of Electrolysis as laid down by Michael Faraday.

These Chemical actions and reactions are not instantaneous, the action is a gradual one, and is controlled by the rate of Current Flow, and also upon the Length of Time during which the Current is permitted to flow.

This applies equally to the Charging as well as the Discharging.

The higher the number of Amperes used, or the longer the time in which the Amperes flow through the cell, the greater the amount of chemical action will result.

It will be obvious that sooner or later all the Lead Sulphate will have been used up, or REDUCED as it is technically termed, and no more Sulphur will be sent into the solution.

When such a condition obtains the cell is said to be fuely charged.

If we continue to send the charging current through the cell when it has reached the state of being Fully Charged the Water in the Sulphuric Acid will be decomposed into its natural elements, HYDROGEN and OXYGEN. These will rise to the surface of the Electrolyte in form of "bubbles" the cell is then said to be gassing freely, this being one of the principal indications of a cell being in a Fully Charged Condition.

Recently thre has appeared numerous "quacks" who claim to be in possession of so called Non-Sulphating Storage Battery, yet still use Lead and Sulphuric Acid as active elements in their "wonderful" invention.

Such a claim is so absurd that serious chemists do not take the trouble to give the matter the publicity it deserves.

In any lead-acid storage battery, it is a chemical impossibility to obtain electricity unless there is sulphation of the elements.

To claim that a Lead Acid Battery can work without Sulphation, is just as absurd as claiming that COAL CAN BURN WITHOUT Oxygen.

Voltage of Cell

When continued CHARGING has finally resulted in the presentation of the usual indications of a fully charg-

(Continued on page 34)

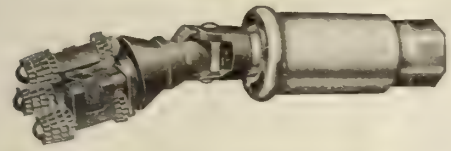
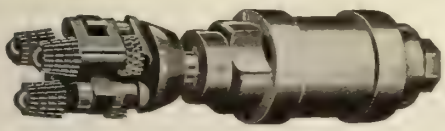
Standard Water Driven Tube Cleaner

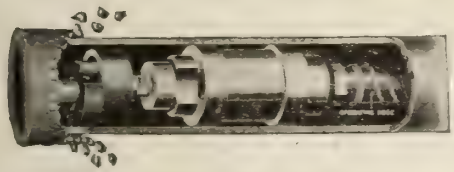
KEEP YOUR BOILERS CLEAN



Lagonda Water Driven Cleaner for Curved Tubes



Lagonda Air Driven Cleaner for Straight Water Tubes



Cleaner Removing Scale from Outside of Fire Tube

All natural waters contain some impurities which, when introduced into a boiler, may appear as solids deposited on the heating surface. No matter what the substance consists of, it must be removed at frequent intervals or it will decrease the capacity and efficiency of the boiler and may cause it to be badly damaged by over-heating.

Some waters, notably well waters, deposit such quantities of scale that they should be purified before going into the boiler, thereby preventing an accumulation of incrustation and consequent damage to boiler parts, and at the same time effecting a large saving in fuel by keeping all parts of the heating surface in a clean and efficient condition. If you have bad feed water it is a case for the chemist, for the scale is probably composed of several substances which must be known before the exact treatments necessary to get rid of them can be determined upon. The use of treatment without technical advice is poor policy.

Stony and vegetable matter in suspension can be removed by FILTERS, which we supply in various sizes and designs to suit all requirements. In most Canadian plants, lake or river water is used for feed, and these waters seldom carry large quantities of scale-forming materials in solution. Scale can be allowed to form in the boiler for a considerable period. Experience in each individual plant determines the limit at which tube difficulties will begin or a perceptible falling off in efficiency will take place. With such a limit of scale formation fixed, and the danger of allowing it to be exceeded, well understood, probably the most economical and efficient method of keeping the heating surfaces clean is by use of the LAGONDA TUBE CLEANERS.

The cleaners are designed and so constructed as to thoroughly remove all the scale, in the shortest possible time, at the lowest cost of operation, and they require a minimum amount of repairs, reducing both the waste boiler time and labor cost of cleaning.

They are made to operate by either water, air or steam, and electricity. In every case a swing head is furnished so designed that three sets of cutters are thrown out by centrifugal force against the scale in such a manner that they make straight line contact with the tube and they do the work without damage to it.

You can be supplied with LAGONDA tools for cleaning Economizers, Condensers, Evaporators and other tubular plant.

PRACTICAL ELECTRICITY

(Continued from page 32)

ed Cell, we will find if we place the wires of a low reading VOLTMETER across the Terminals of the Cell, that is a Voltage Reading of 2.60 to 2.70 Volts.

If we now stop the Charging Current and again apply the Voltmeter we will only obtain a reading of about 2.15 Volts.

The reason for this being due to the formation of lead sulphate in a very thin layer all over the surface of both plates.

This Voltage is of little value to us as an indication of the condition of the Cell, this is called the OPEN CIRCUIT VOLTAGE.

To obtain a truer indication it is necessary to obtain a reading when the cell is doing work. We therefore take regular readings of Voltage when the cell is Discharging at the average normal rate of Discharge for which it is designed. If the Cell is fully Charged it will show a reading of 2.00 to 2.15 Volts.

When current is being drawn from the Cell whilst DISCHARGING, the Voltage of the Cell immediately begins to fall, and falls at a very rapid rate at the beginning of the Discharge, and then follows a "straight line" for several hours, after which it again falls rapidly down to Zero.

This Characteristic is shown in Curve of a cell discharged in 8 hours (Fig. 11).

The reason for this fall of Voltage is due to the formation of Lead Sulphate ($Pb\,SO^4$) on the surface and also within the "pores" of the active material. As the sulphate forms in the body of the plates, the Acid is used up. This results in a general weakening of the Strength of the Acid, consequently the Chemical Action between the Acid and the Lead Peroxide is naturally reduced.

Furthermore, the Lead Sulphate is of considerable higher Resistance than the Lead Peroxide, and as a result, as the Active Material becomes more and more "Sulphated" this Resistance increases, resulting in an increase of the Internal Resistance, which in turn causes the Voltage to fall.

As this Sulphation is continued a complete cover of Lead Sulphate gradually forms over the surface of the plate, preventing the accession of a further supply of acid reaching the interior layers of active material.

Theoretically, it is possible to Discharge a cell down to Zero Voltage, but in practice it is never permitted to Discharge a cell after the Voltage has fallen to 1.65 Volts.

If the discharge is continued beyond this point both the positive and negative plates will have become so impregnated with lead sulphate that they cannot further respond to the action of the acid remaining in the tank, because of its strength having been reduced to almost the density of water.

Furthermore the plates which have become sulphated to such an extent need very careful handling on re-charging the cell, because lead sulphate is a

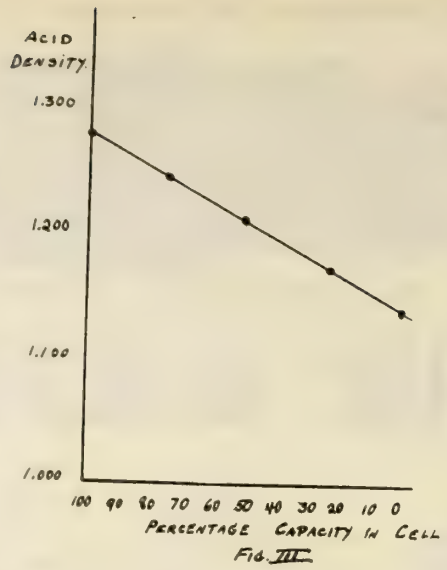

Fig. III.

non-conductor of electricity, as a result the internal resistance of the cell is increased. If we recall the earlier lessons, we will remember that if we increase the resistance of a circuit we increase the amount of heat generated by the passage of a current round that circuit.

Specific Gravity of Electrolyte

The electrolyte must be of sulphuric acid made from sulphur. Acid made from pyrites should never be used as it contains injurious substances.

The density or specific gravity is a varying quantity varying for the design of cell, and for the degree or discharge of any particular cell. (Fig. III).

Sulphuric acid of "full strength" has a specific gravity of 1.835. This is much too "strong" and cannot be used in a cell until it is diluted with distilled water down to the correct Sp. G.

The specific gravity usually employed is 1.200 and 1.225 for storage batteries for use power houses, telephones, fire alarms, etc., whilst for automobile self starters, or electrically propelled vehicles, specific gravities ranging from 1.280 to 1.300 is the standard practice.

It will now be apparent why the specific gravity will vary according to the state of charge.

It has already been shown that as the cell discharges the plates become sulphated. Now where does the sulphur come from? From the sulphuric acid. The sulphuric acid being merely a mixture of sulphur and water. Therefore if we abstract some of the sulphur the percentage of water remaining in the electrolyte will be increased and as the specific gravity of water is 1.000, the more sulphur abstracted from the solution the nearer will the density of the solution approach that of water.

Therefore whilst the battery is being discharged the SO_4 is abstracted from the electrolyte, and when it is being charged the sulphur is driven back into the electrolyte.

From a study of this fact it will be obvious that the actual state of the specific gravity is an indication of the state of charge or discharge of the cell.

In addition to the specific gravity it is necessary that the correct volume of sulphuric should be provided, as the more electrolyte present in the cell the better will be the performance. This quantity is unfortunately varied over a wide range, and what is lacking is volume is made up by increasing the density of such electrolyte present.

Self starter batteries electrolyte density 1,280 volume 4 lbs. of electrolyte per 100 ampere-hours capacity.

Power house batteries electrolyte density 1.215 volume 15 lbs. of electrolyte per 100 ampere-hours capacity.

Capacity of a Cell

The capacity of a storage battery is the amount of electrical energy we can get out of it. This is measured in ampere-hours.

Theoretically, a battery has a capacity of 100 ampere-hours if it is capable of delivering 10 amperes steadily for 10 hours, and then be unable to deliver more current.

Based upon this theory the cell capacity would be the number of amperes it is capable of delivering steadily for the number of hours it is capable of so doing, and at the end of that period to be incapable of delivering more current.

In practice however this is not so, because we never discharge a cell down to zero. A limit on the final voltage has to be fixed, this is called the final terminal voltage, and again is a varying quantity, varying with the rate of discharge.

This is limited by the following formula:

$E = 1.66 + 0.0175 \times T.$

When E final voltage. T time in hours of proposed discharge.

The capacity of a cell depends upon the following factors:—

(1) Area of plate surface.
(2) Quantity and porosity of active material.
(3) Quantity of electrolyte.
(4) Density of electrolyte.
(5) Circulation of electrolyte.
(6) Temperature.
(7) Rate of discharge.

In a well designed cell made by the large manufacturers factors from 1 to 5 are all in accordance with well established scientific practice.

The rate of discharge is one of the most important limiting factors of the capacity.

It has therefore become necessary to establish some standard time for the rate of discharge. This is considered to be the 8-hour rate. If the rate of discharge is increased the ampere-hour capacity is diminished. If the rate of discharge is reduced the capacity is increased.

Generally speaking the capacity of a well designed cell when discharged in 8 hours is just twice the capacity of the same cell when discharged in 1 hour.

H. W. PETRIE, LTD., 131 FRONT STREET W., Toronto, sell new and used boilers, engines, air compressors, electric motors, machine tools, wood-working machinery, transmission equipment and small tools; get our prices for machinery on monthly rental.

When answering this advertisement, mention this paper. P.F.H.

SITUATIONS WANTED

STATIONARY ENGINEER — SECOND CLASS, requires position, ten years' experience of steam generation, refrigeration, cold storage and electric generation, thoroughly experienced with heating systems and hydraulics and all classes of stationary engines, used to large plants, good references. Apply to Box 5122. P.3H.

DIE SINKER — THOROUGHLY PROFICIENT in all kinds of first class work. Apply Box 107, Power House. PFH

AGENTS WANTED—ONE OF THE LARGEST manufacturers of steam jet ash conveyors in the country desires representation in Canada. Only those calling on Power plants daily, and thoroughly familiar with this line of equipment need apply. Liberal Commissions. Apply Box 106, Power House. Toronto. P.F.H

STATIONARY ENGINEER, SECOND-CLASS, requires position; thoroughly experienced in operation of heating, refrigeration, compressed air, and knowledge of electricity, as applied to institutions. Can handle switching locomotive. Apply Box 109, Power House. P.1.H.

Every Engineer, Mechanic and Electrical Worker will welcome this new master set. It will answer your problems.

It will help you with your daily work.—A sure source of advancement and higher pay. Complete up-to-date information that is thoroughly and easily explained on every branch of modern engineering and electrical practice.

AUDEL'S ENGINEERS & MECHANICS GUIDES
4750 PAGES **$1 A MONTH**
8754 ILLUSTRATIONS **$12 COMPLETE**

These Guides tell you all about—

Theory, Practice and **Operation** of ALL Steam Engines; UNIFLOW and POPPET VALVE ENGINES, gas ENGINES, AUTOMOBILES, Locomotive-Marine Engines; Turbines; Rotary Engines--Valve Setting--Indicating--Lubrication--PRACTICAL MANAGEMENT, GAS, GAS ENGINES--Aeroplanes and Aviation; HOW TO SELECT AN ENGINE. STEAM ENGINE rules and formulae. Steam Boilers; Heat--Combustion; Fuel and Furnaces; Coal Pulverizers--Construction of all types of Boilers--Mechanical Stokers--Oil Burners--Setting--Chimneys--Mechanical Draught--HOW TO SELECT A BOILER--BOILER DESIGN based on A.S.M.E. BOILER CODE--OPERATION FIRING. Pipes, Fittings--Heating and Ventilation--Refrigeration--Cooling Towers--Condensers--Distilling Apparatus--Elevators--Cranes--Ropes and Cables--Splicing--Practical Engineering as an aid for engineers and electricians in obtaining a license--ready reference index, covering entire field of Modern Electricity.

SHIPPED TO YOU FREE

Not a cent to pay until you see the books. No obligation to pay unless you are satisfied. Send coupon now--today and get this new master set for engineers. Pay only $1 a month.

SEND NO MONEY

THEO. AUDEL & CO, 72 Fifth Ave., N.Y.

Please submit me for approval, AUDEL'S $12 set MASTER SET FOR ENGINEERS & MECHANICS. Ship at once prepaid, the Steamboat. If satisfactory, I agree to send you $1 within 7 days and to mail you $1 monthly until $12 is paid.

MONCRIEFF'S "UNIFIC" WATER GAUGE **GLASSES**

Moncrieff's "Unific" is not a cheap glass. But because it outlasts many ordinary glasses the "Unific" is economical. British Made.

The "Unific" does not readily corrode It resists extreme changes of temperature and withstands the highest working steam pressure.

JOHN MONCRIEFF LIMITED
PERTH, SCOTLAND
Canadian Representative: W. J. WALL, 134-136 Bleury St., MONTREAL, CANADA

Pressure or Load Changes do not Affect the Accuracy of your COPES

Boiler Feed Water Regulator

A very wide working range is afforded by the simple design of the COPES Regulator, which operates on the thermostatic principle.

Not affected by changes in boiler pressure. A high factor of safety adapts the COPES to the highest steam pressure used in modern central station practice. Operates efficiently at a working pressure of only 10 lbs.—or more than 300 lbs.

Even if the pressure CHANGES AS MUCH AS 100 LBS., the COPES requires no readjustment. (Most mechanical feed regulators require readjustment for pressure changes as low as 20 lbs.)

Automatically the Copes varies the water level in the steam furnace to suit during light loads and to increase the boiler steam capacity during heavy load demand.

Our new catalog, just off the press, gives the facts about boiler feed water regulation that you need. Write for Catalog D.

COPES

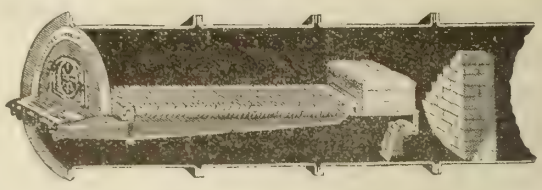
NORTHERN EQUIPMENT COMPANY

112 West 11th St.

Erie, -- Penn.

Branch Plants: Hamilton, Ontario, Canada; Manchester, England; Paris, France; Cologne, Germany.

Lower Fuel Bills



THE

TURBINE (Patent) Furnace

A fuel-money-saving furnace for externally or internally-fired boilers. Enables coal slack, coke dust and low grade fuel to be burned with all the advantages of forced draft. Highest fuel economy. Over 1,100 of these furnaces giving satisfactory service in Britain now. We shall be pleased to furnish full particulars.

Manufactured by:—

The Turbine Furnace Co., Limited, London, England.

Sole Canadian Agent :

PERCY A. GOEPEL

525 Pender Street West, Vancouver, B. C.

New Truths and Old Fallacies

A PARTING SHOT

Now, in conclusion, please excuse us for paying our respects to certain competitors whose shibboleth is "just as good," or "the same thing" as Magnolia.

Admit, if you please, for the sake of argument, that they know, at least, the approximate formula of Magnolia—then what? Does an analysis show our foundry practice and thermal treatment? Does it show our graphite treatment? Have most of these people ever heard of impurities of low atomic volume, or have they the remotest idea as to what an eutectic is, as applied to babbitts?

Their literature, that we have seen, denotes their entire ignorance of these subjects, and never, by any chance, give comparative figures of tests, with and without lubrication, or have anything to say regarding co-efficients of friction. Apparently the extent of their information is confined to a knowledge of the formulas of the general run of "commercial babbitts," and the finer points of compounding are evidently not dreamt of in their philosophy.

Some of them will make any claim and quote any price to obtain business, without regard to the interest of their customers, and this is often done by well-meaning people who are uninformed on the subject.

No other concern than Magnolia Metal Company has ever given out so much useful information regarding babbitt metals. When it comes to the cold analysis of figures and facts, is not the discreet silence of other concerns a fair inference that they have nothing of equal value to report?

We lay our cards on the table face up, and ask that our competitors be at least required to do the same thing.

It never pays to buy the cheaper grades of anything, as a dime saved in price is often a hundred dollars lost in efficiency.

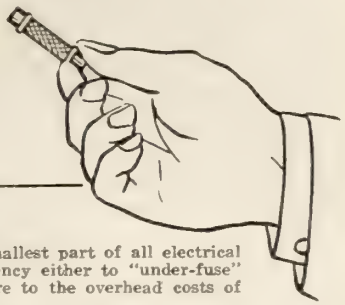
MADE IN CANADA

"Simplicity" Renewable Fuses

The Tiny Refill At the Cost of A Postage Stamp



A great many electrical troubles may be traced directly to the smallest part of all electrical equipment—the ordinary plug fuse. One great fault is the tendency either to "under-fuse" or "over-fuse." "Under-fusing" circuits is adding more and more to the overhead costs of Canadian Power Houses every year.

"Over-fusing" circuits is dangerous. Improperly fused circuits are the cause of many fires costing thousands of dollars annually.

Simplicity—Safety—Protection— **"Simplicity" Renewable Fuses** are simple. They consist of only two parts and the tiny refill. Not a tool is needed for the refilling operation. They are ultra-safe. The refilling may be carried out with wet hands without the slightest danger.

They are a protection because the correct rating is **always visible.** They reduce accidents to a minimum.

A "Canadian Made" Product—Approved by National Board of Fire Underwriters and Hydro Electric Power Commission of Ontario. A plant has now been erected in Toronto for the manufacture of "Simplicity" Fuses.

The economy and absolute safety of "Simplicity" Fuses should appeal to every Power Plant owner or operator in Canada. The first cost is practically the last, but, before everything else, they are SAFE.

Send for illustrated pamphlets.

HEPBURN PATENT PUMPS

Something To Be Proud Of

This vertical outside-packed ram pump is specially designed to handle high temperature water at high steam pressures. It is a double-acting pump, although it has only one gland to require packing. It occupies a minimum of space; has no levers or tappets to get out of order; provides perfect cushioning of the steam piston; has an automatic draining device and runs with a full stroke even at the slowest speed. It is undoubtedly the finest pump on the market.

If interested, write us, or better still, visit our plant and see the Hepburn Pump being made.

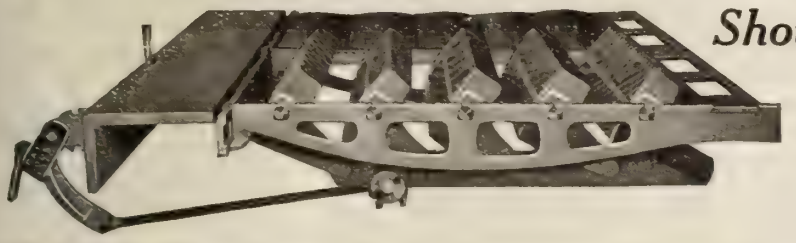
A Reasonable Saving of 5 to 10%

Should You Expect More?



The Canadian Steam Boiler Equipment Co., Ltd.

Sole Makers for Canada

20 McGee Street PHONE: G. 3660 Toronto, Ont.

WE GUARANTEE that with the use of CYCLONE SHAKING AND DUMPING GRATE any grade of hard or soft coal, **or screenings of same,** can be burned with excellent results both as regards Economy and Capacity; that the total annual expense to the user for coal, interest, depreciation, repairs, damage to boiler, liability of shut-down, etc., will be much less than would be the case with any other type of Grate or Stoker on the market.

Cut Your Coal Bills

Leaky boiler settings are the cause of unbelievable fuel waste. All possible heat generated in your furnaces will go to the making of steam when your settings are constructed of

PLIBRICO JOINTLESS FURNACE LINING

Tight PLIBRICO baffles, front and back arches, side walls and bridge walls will effect a material saving on your coal bills. Worth looking into, isn't it?

Send for our booklet L-46 on "Modern Furnace Building" and ask our nearest representative to call.

PLIBRICO is delivered only in steel containers of distinctive appearance as shown at the right.

DISTRIBUTORS:—Beveridge Supply Co., Ltd., Montreal, Que.; Shell Bar Bolco Supply Co., Ltd., Toronto, Ont.; Evans, Coleman & Evans, Vancouver, B. C.; Winnipeg Supply & Fuel Co., Winnipeg, Man.; Gorman's Ltd., Calgary, Alta.

For

Self-Promotion And Sales Promotion

Are you interested in any of these fields—power—metal working—marine? As a manufacturer, or purchasing agent, as a superintendent or foreman, as an ambitious mechanic or engineer?

Use These Publications

They will keep you strictly up-to-date in all branches of mechanical engineering. Edited by practical men. Cheerful, inviting, instructive, authoritative.

POWER HOUSE

Twice a month—$2.00 per year.
Serves the power plant engineer—Steam, Electric, Refrigeration, Hydraulic.

CANADIAN MACHINERY

Weekly—$4.00 per year.
Covers the metal working field—serving shop executives, purchasing agents and owners. First-class mechanical paper and market paper combined.

CANADIAN FOUNDRYMAN

Monthly—$2.00 per year.
A paper for the foundry owner, superintendent and foreman. Claimed by its readers to be unexcelled.

CANADIAN SHIPPING AND MARINE ENGINEERING NEWS

Monthly—$2.00 per year.
Interprets marine engineering in its broadest sense, serving the shipbuilders, navigation companies and their officers. (The Editor holds an extra first-class B.O.T. certificate).

Published by

THE MACLEAN PUBLISHING CO., LIMITED

143-153 UNIVERSITY AVE., TORONTO

A company whose idea of service has made it the largest concern of its kind in the British Empire.

Thirty years' experience and dozens of practical men in your own line, stand ready to serve you. Let them! Subscribe for your paper to-day.

Men with selling problems will find a profitable tip in the statement made by a prominent manufacturer recently. "I use MacLean Publications because I am satisfied that papers with such a high standard of editorial excellence, MUST have an influential following."

De Laval Two-Stage 6 in. Centrifugal Pump Driven by Gasoline Engine. 960 Gal. Per Min. Against 349 Ft. Head. Installed at Pembroke, Ont.

Pumping by Gas Power

THE GAS, gasoline or oil engine offers convenient and inexpensive power for pumping. The speeds of gasoline engines harmonize very well with those of centrifugal pumps, and gears are usually unnecessary. There are no pump valves and only the two simple packings about the shaft. The bearings, the only parts requiring lubrication, are ring-oiled. The few parts subject to wear, such as bearings, shaft sleeves and impellers, can easily be renewed, as De Laval pumps are built upon a limit-gage, interchangeable basis. All working and wearing parts are accessible upon lifting the casing cover and bearing caps. The water delivery is smooth and without shock or pulsation, and no injury results should the discharge be suddenly cut off or opened wide.

All De Laval pumps are guaranteed as to capacity and efficiency and are thoroughly tested before leaving the works.
State your pumping requirements in detail and our engineering department will make recommendations.

Ask for Catalog. B103.

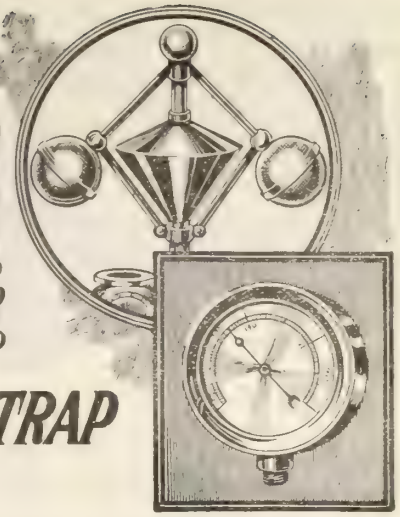
You can See these things operate—but, You can't See the Inside of a STEAM TRAP



If anything goes wrong with most mechanical devices you can **see** it. But with a steam trap it's different. Here the trouble is hidden, and, in ordinary traps, difficult to locate because of the hard-to-get-at construction of the trap itself.

Simplicity is the keynote of "Sarco" construction. It has only one moving part. There is nothing to get out of order or require repairs in the

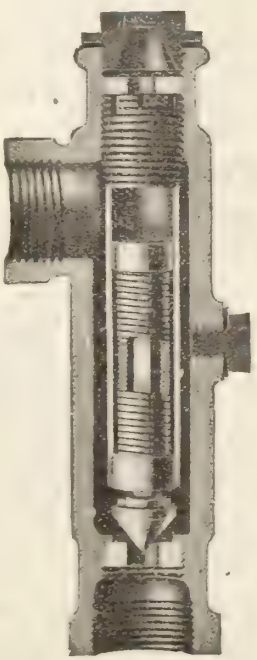
STEAM TRAP SARCO

The conical valve head is of quick and positive action—operated by a sensitive expansion-and-contraction element. Valve seat has *line* contact instead of *surface* contact, which prevents scale from becoming lodged between seat and head. That's all there is to it. No floats, levers, valves, water gauges or packing to cause trouble. No air-binding, clogging or leaking. No steam hammer, no freezing.

The drum is corrugated spirally instead of annularly, thus distributing the wear evenly over the whole surface.

The Sarco takes little more space than an elbow, so can be installed where a big trap would not go. No pit digging or platform is required.

And you can buy *three* Sarco Traps for about the price of one "Bucket" or "Float" Trap.



Write today for Booklet J-29 and our plan which enables you to try the "Sarco" at our expense for 30 days.

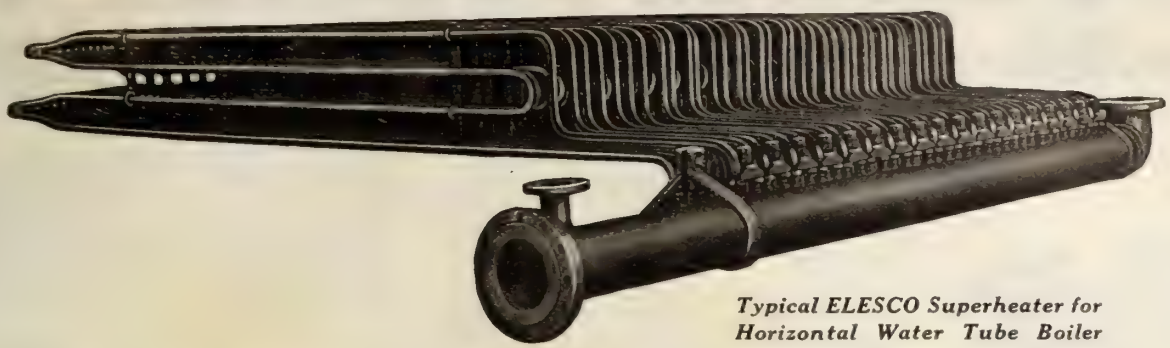
Importance of Design in Superheaters



Typical ELESCO Superheater for Horizontal Water Tube Boiler

Maximum superheating efficiency and capacity, ease of application, accessibility, and long life, essential points in superheater design, are found in the ELESCO Superheater.

FOR EXAMPLE.

Headers are usually located outside of the hot gas path, and in many cases outside of the boiler setting, where they are accessible. The inlet to the saturated header and the outlet from the superheated header are at opposite ends, assuring an even distribution of steam flow through all units.

Units are **uncovered** and present a smooth external surface, making cleaning easy and resulting in high efficiency in heat transfer from the gases to the steam.

The connection between the units and headers is a metal to metal ball joint, which is made without rolling or destroying metal, and which can be made or broken without special tools.

In these and many other features of design, the ELESCO Superheater represents an important advance in superheater engineering.

Which Stoker?

—You Make this Decision Once—It Must be Right

JONES Stokers are made in Canada by Canadians and are sold for Canadian money at par. Through special arrangement the extensive engineering resources of the Under-Feed Stoker Co., of America are made available for Canadian power users. Thus this strictly Canadian stoker is backed by world-wide experience and unequalled engineering ability.

EXPERIMENT with any equipment is costly-- but experiment with mechanical stokers is out of the question. The investment is large; it is made once in a lifetime; snap judgment won't do;—*Which stoker?*

Canadian plants want greater boiler capacity--continuous power day and night when necessary--they want this accompanied by greater economy in burning Canadian coals and by lower labor and maintenance costs.

This means *high duty stoker firing*, best exemplified by the Jones "A-C" (Automatic-Cleaning) Stoker.

Regardless of the size of the plant, the grade of coal burned or the local conditions to be met, the logical, safe answer to *"which stoker?"* is Jones "A-C."

The new "A-C" catalog goes into detail, Jones engineers with unmatched experience in this specialized field, will gladly make a survey of your plant and give you the full benefit of the best they have learned in installing stokers in many prominent power houses. Investigation implies no obligation.

For Better Power Transmission

"P. M. S" Rubber Belting owes its extensive popularity in this country to its excellent adhesion to the pulleys, even pliability, great strength and unequalled ability to resist the effects of heat, cold and moisture. These qualities, coupled with its comparatively low first cost and usefulness for nearly all purposes, have won the respect and esteem of Canada's engineers. It is giving excellent service to-day under conditions once believed too severe for this type of belt.

Regrinding Globe Valve

REGRINDING BRASS VALVES

"PENBERTHY" Regrinding Valves were designed to meet the ever-increasing demand by Power Plant owners for a Valve that would not only stand up under high pressure and severe conditions, but would obviate the necessity for unnecessary renewal of discs and repair parts.

"Penberthy" Renewable Valves were the first in the field and met with instant approval. Many imitations have appeared from time to time but the superior quality of design, material and workmanship of the "Penberthy" original has at all times asserted itself.

"Penberthy" Regrinding Valves are made from the best quality steam metal, generously distributed so that parts subjected to the greatest strain and wear have proportionately heavier walls. The union bonnet ring which secures bonnet to body is of heavy design and this outside bonnet construction (found in all Penberthy Valves) is acknowledged by leading engineers to be the safest, and most practical improvement made in brass valves in generations past.

Perfect Satisfaction Guaranteed

"Penberthy" Regrinding Valves are guaranteed to give perfect satisfaction and to stand the full working pressure as cast on every valve bearing the Penberthy trade mark. They mean a saving of time, labor, trouble and repair bills. Be sure that every valve you buy bears the Penberthy Trade Mark.

The economy valve

LUNKENHEIMER "Ferrenewo" Valves

are a real "economy buy" in first cost as well as maintenance. The "Valve-iron" body while costing less than bronze provides a high safety factor for the 150 pound pressure rating for which these valves are recommended, and the seat ring and disc — the parts subjected to the greatest wear—are made of Lunkenheimer "Valve-nickel," a material possessing extreme wear resisting qualities, insuring long service life. Besides, the seat ring and disc and all other bearing parts can easily be renewed.

Globe, Angle and Cross Valves and Horizontal and Angle Check Valves in sizes from ¼ to 2 inches inclusive.

For handling cyanides, acids and other solutions which attack bronze alloys these valves are furnished in "All Iron."

Descriptive booklet No. 567-DC. sent upon request.

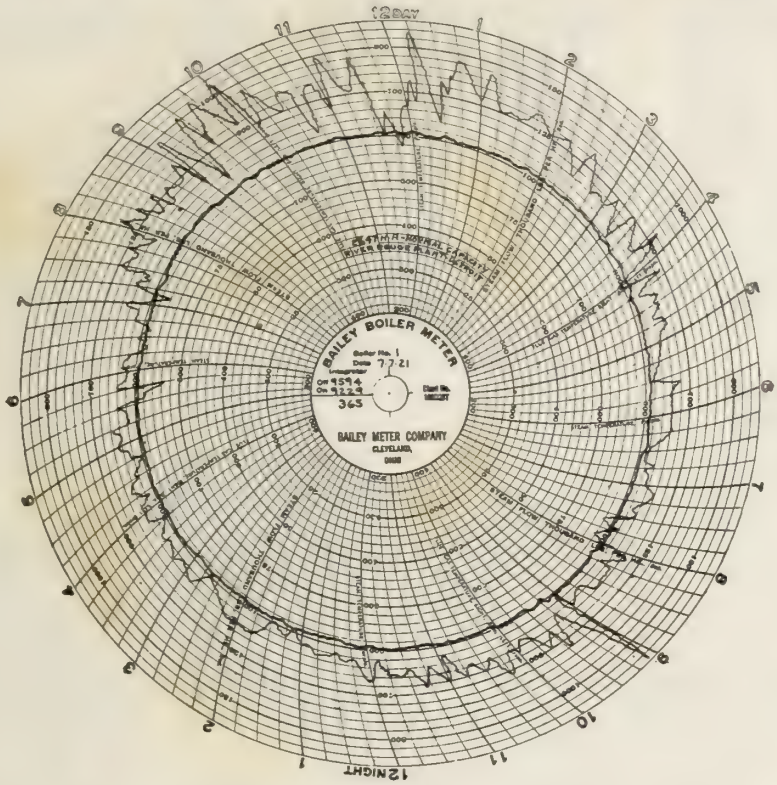
Constant Steam Temperatures Maintained with ELESCO Superheaters at the Ford Motor Company, River Rouge Plant



Maintenance of superheated steam temperatures nearly constant under a wide range of boiler loads, is shown on the above chart taken from one of the 2,647 H.P. boilers at the River Rouge plant of the Ford Motor Company.

The outside irregular line indicates the steam flow, which under normal operation at 100% boiler rating is 82,586 lbs. per hour. It will be seen that this varies from 163,000 lbs. maximum 197.5% rating to 84,000 lbs. minimum 101.6% rating.

The even inside line indicates steam temperatures. At normal pressure (225 lbs. gauge) the approximate temperature of 200 deg. superheat is 600 deg. F. It will be noted that the variation in steam temperature, from 615 deg. maximum to 588 deg. minimum, is but 4.5%.

Correctness in design and location of ELESCO Superheaters reduce the variations in steam temperatures to a negligible quantity.

The True Coal Consumption of Your Individual Boilers

Is the basis upon which your plant economy depends.

The BAILEY METER for Coal

Eliminates all guesswork—it eliminates, too, any necessity for the installation of extremely expensive and complicated weighing apparatus above each coal chute.

The meter gives surprisingly accurate and consistent results when installed in a vertical pipe under proper conditions. It is built to withstand hard usage and as there is no external power required it will operate with a minimum of attention. It can be installed easily in existing coal chutes at a very moderate expense.

The counter is self-illuminated and has figures 1½ inches high so it may be read at a distance of 50 feet.

Write for Bulletin No. 220 which gives full description.
Consult us regarding its application to your boiler room.

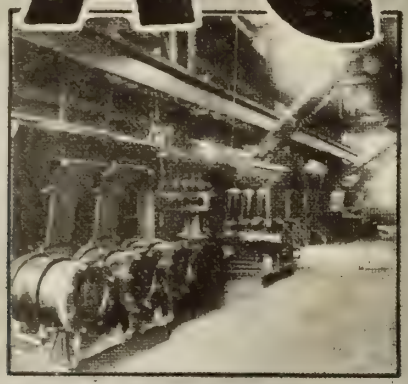
Jones "A-C"



High-Duty Stokers

—for heavy overload capacity

THERE is no safer index of stoker performance than ability to meet and sustain heavy overloads. For the stoker that will not carry heavy overloads, is almost invariably lacking in other essentials of economical operation. Heavy overload capacity is an inherent advantage of under-feed stoking, that basic principle originated and perfected in Jones Stokers. No ignition arches are needed for under-feed stokers, so the full radiant effect of the heat is obtained.

Jones "A-C" retorts hold 50% more coal. Consequently volatilization is complete even at highest over-ratings. Eight ranges of fuel and air supply insure highest efficiency for all combustion rates. The elimination of troublesome clinker formation, coupled with rugged simplicity of design, insures year round overload capacity.

The heavy overload capacity of Jones "A-C" Stokers often makes the installation of additional boilers unnecessary when the load is greatly increased through plant expansion.

Write for the "A-C" catalog.

Made in Canada

All Jones Stokers are made in Canada by Canadians and sold for Canadian money at par.

USE LESS FUEL

You can do it, while at the same time producing more power, if your boiler settings—arches, side and bridge walls and baffles—are made of

PLIBRICO JOINTLESS
FURNACE LINING

There is no chance for air or gas leaks through a PLIBRICO setting, therefore less fuel is needed to obtain the objective desired—the production of steam.

Not only does PLIBRICO permit the production of more steam at less cost, but it forms boiler settings that last from two to four times as long as laid-up fire brick, and that are impervious to heat up to 3,100° F.

A complete PLIBRICO setting is a paying investment. Our book, L-68 on "Modern Furnace Building," gives full information. Ask for it, and ask also to have our nearest representative call.

Our service is free.

PLIBRICO is delivered only in steel containers of distinctive appearance as shown below.

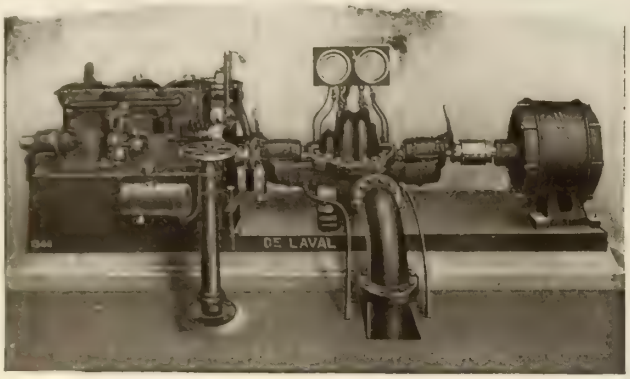
Duplicate Power Supply For Pumping



Ask for our complete catalog B-103

THE De Laval centrifugal pump shown herewith was built for the City of Lindsay, Ont., and is arranged to be driven either by an induction motor, or, when electrical power is not available, by a 6-cylinder gasoline engine. A clutch is provided for disconnecting the engine when not in use. The unit is rated at 1,325 gal. per min. at 1,450 r.p.m. With a duplicate power supply there is practically complete assurance of being able to deliver water at all times. The characteristics of De Laval centrifugal pumps are ideal for such service, as there is practically zero starting torque, and, due to the power-limiting characteristic, the De Laval pump cannot possibly overload the motor.

LEONARD

The Polished Rod

The much desired "glass-like" polish on piston rods can only be maintained by the use of a packing that retains its elasticity and lubricant—not for a few hours after repacking, but during long service of changing pressures and temperatures. Rings of Garlock High Pressure Packing combined with our Diagonal Ring Packing makes a combination (Style No. 446) particularly adapted for service against medium or high pressure steam.

This combination will retain the polish and

FORCED AND INDUCED DRAFT AT HELL GATE

The above shows the location of Sturtevant fans and the important part they have in boiler plant operation.

At present there are eight of these forced draft and twelve induced draft fans in this station, all direct-connected to brush-shifting motors.

The completed layout calls for one forced and one induced draft fan for each of the twelve boilers.

In this, the world's largest power plant, as in other representative installations, it is Sturtevant apparatus that is usually included.

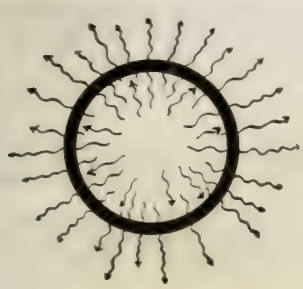
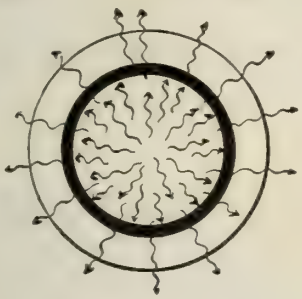
What pipe insulation efficiency means

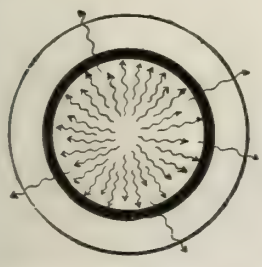
Pipe insulation efficiency is the percentage of the bare pipe heat loss which is saved by the insulation. It varies with pipe size, insulation thickness, and temperature difference.



1. This represents bare pipe. The heat loss, as represented by the escaping arrows, is maximum. The efficiency is zero.



2. Low grade "pipe covering." This may look like high-grade insulation but the heat knows the difference. Too much heat escapes — efficiency is low.



3. Johns-Manville Asbesto-Sponge Felted Insulation. In a test of 26 heat insulations conducted at the University of Wisconsin, this insulation led all others in efficiency.

Buy pipe insulation efficiency —not just pipe covering

IN selecting pipe insulation, the careful buyer never forgets that one consideration dominates all others — permanent insulation efficiency. Obviously, this is the quality that actually pays dividends in economy.

Initial efficiency, unless maintained year after year, means nothing.

That is why the permanent high efficiency of Johns-Manville Asbesto-Sponge Felted Insulation is so important. Impartial tests (such as those conducted at the University of Wisconsin) have repeatedly shown its construction the most efficient on the market.

In Asbesto-Sponge, the thin laminations of indestructible asbestos fibre carry countless dead-air cells formed by the imbedded spongy material. These cells and the dead-air spaces between laminations form an unusually effective heat barrier.

But of equal or even greater importance is the fact that the construction is exceptionally strong which assures durability. Dampness, shocks and vibration leave it unharmed — you can even hit it with a hammer.

Asbesto-Sponge retains its high efficiency indefinitely. For that reason it is most economical.

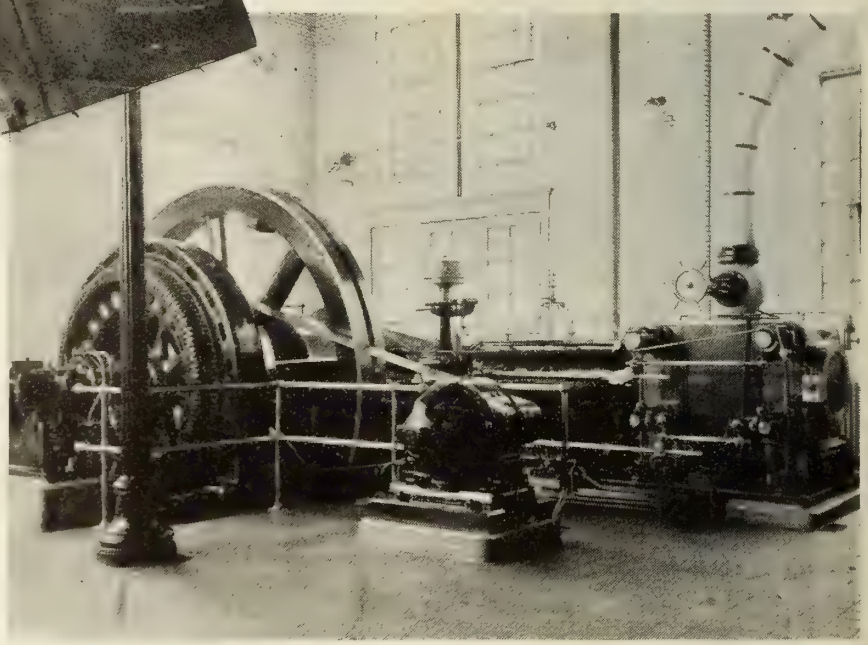
G. & McC. Sectional Water Tube Boilers of 412 Horsepower each.



Heavy Duty G. & McC. Corliss Steam Engine.

Write for Catalogue, Prices and Detailed Information

G & McC. Se tional Water Tube Boilers are built to meet the demands of the largest plants. Greater combustion area and increased steaming capacity are two important features that distinguish them from ordinary boilers—**they can be forced** w thout danger.

G. & McC. Corliss Engines are well known to leading engineers of Canada for the exce'lence of their general design and perfection of materials and workmanship. They are the logical selection for big plants similar to that of the Toronto Carpet Company. There are many points of superiority about them which make them also the most desirable engines **for plants of every size.**

One of Toronto's Outstanding Power Plants

The Toronto Carpet Manufacturing Co. Has a Power Plant Which is Modern in Every Respect—Everything Necessary in the Way of Recording Instruments Are Installed and Appearances Have Been Well Looked After

By T. H. FENNER

AMONG THE industries that have been developed in Canada during the last few years, and are now assuming healthy proportions, the carpet and cloth making industry holds an important place. There was a time when one thought of cloth for garment purposes, and carpets for domestic use, as purely imported materials, but such is no longer the case. While the greater part of these goods are still imported, there is a constantly increasing proportion being manufactured in Canada.

Among the largest manufacturers of these two staples, the Toronto Carpet Manufacturing Co., King Street, Toronto, occupies a prominent place. Part of the premises are devoted to the manufacture of carpets, and part to the production of "Barrymore" cloth. Two very important requirements for a factory of this kind, are power for the looms, and steam for heating water, drying, and various processess entering into the manufacture, as well as steam for heating the premises during the winter months. To take care of these requirements, a very modern steam and electric generating power plant has been installed, and this in addition to a certain amount of power purchased from the Hydro Commission, amply performs the duty.

The general design was prepared by Mr. M. F. Thomas, consulting engineer for the Toronto Carpet Manufacturing Co., while the general contractors were the Wm. Steele and Sons Co. The plant is an interesting example of a modern industrial power plant of medium size, and is convenient in arrangement, while providing ample room for the equipment contained in it.

The General Arrangement

The power house building is in shape like an L, the engine room being the

short leg of the letter. The engine room is on the ground level, and the door in the front of the building shown in the photograph leads direct into the centre of the room. The height can be seen from the outside view, while the photograph showing the engine gives clear evidence of the light available.

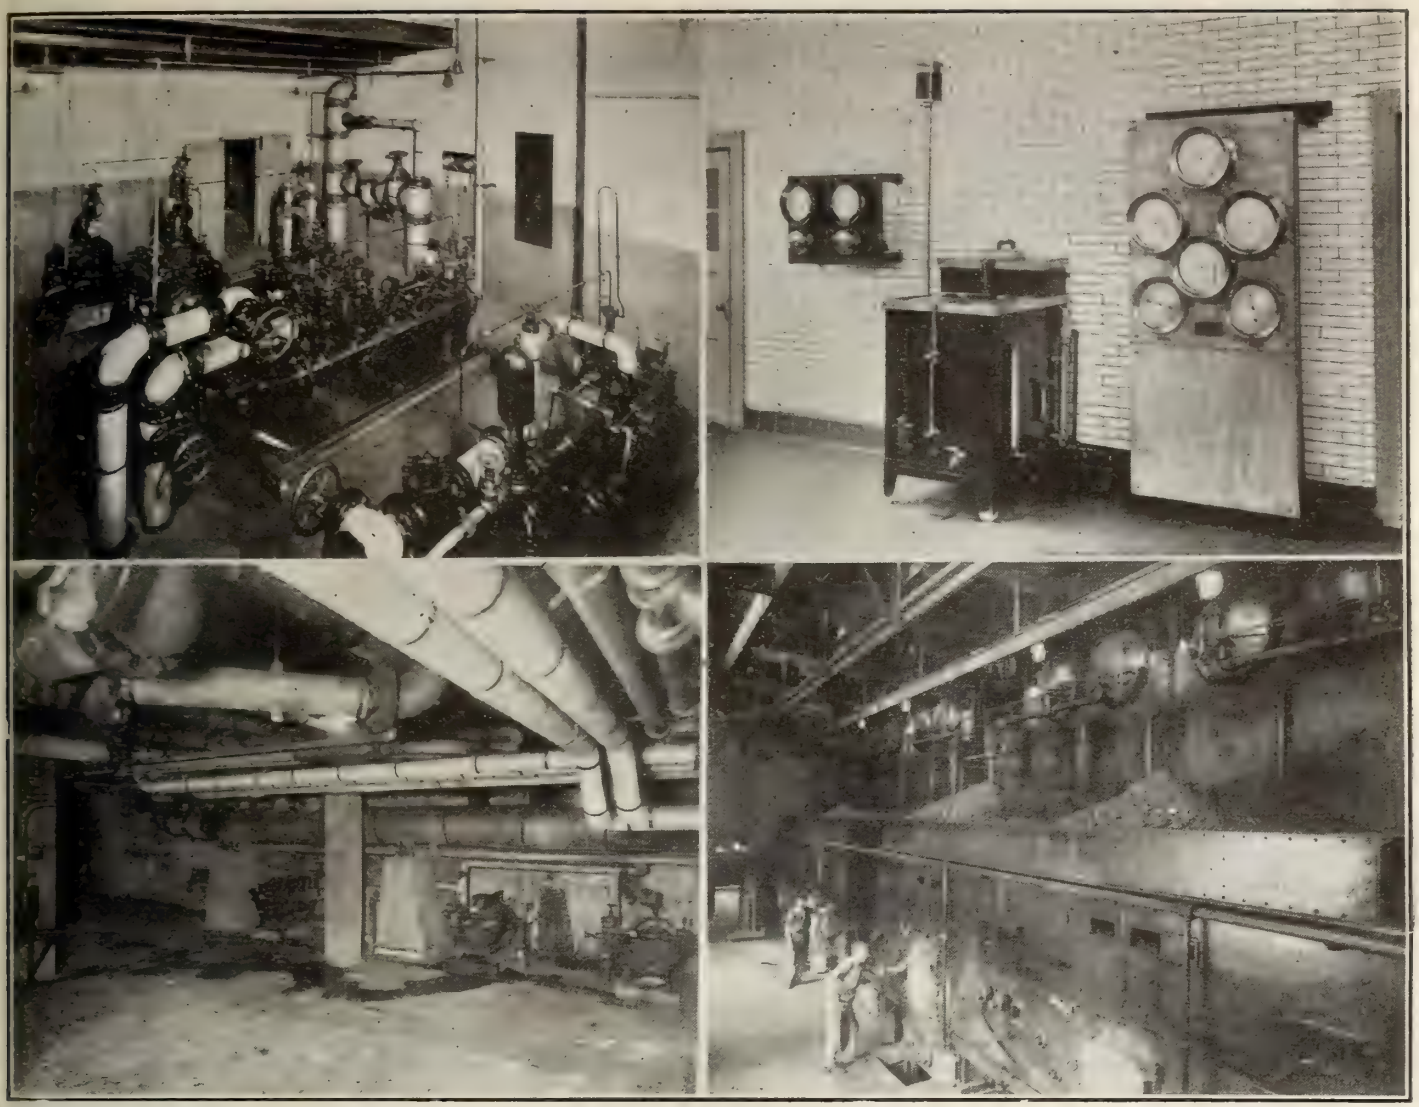
Behind the engine room, in the main part of the building is the pump room, which is divided in two, one portion containing the feed and vacuum pumps, while a separate chamber in the rear houses the fire pumps. There is also a wash room, containing shower and all conveniences, in the rear of the pump room, and divided off by a partition. The pump room level is about six feet below the engine room level, a fact which gives the opportunity to have the heater just inside the pump room partition, but on the same level as the engine room floor, and thus well above the pump room, and pump suctions.

The boiler room, which is divided from the pump room by a strong wall, making it practically self contained, is on the same level as the pump room, and a door leads between the two. The front wall of the boiler room contains four large openings, opposite each wall of the boilers, which can be closed by a metal screen, on rollers, or left wide open in the warm weather. The extreme right hand opening can be seen in our photograph, to the right of the engine room. The proximity of office and factory buildings prevented our photographer from getting a full front view of the engine and boiler rooms. This plant is situated right in the centre of all the buildings, which position, while very desirable from a utilitarian point of view, does not lend itself to getting a satisfactory photograph.

There is a basement under the pump room, which extends also under the boiler room, and contains the lower run of the conveyor, and a tunnel for the piping going to the factory.

The Boiler Room

The boiler room is well equipped with recording and indicating instruments and coal and ash handling machinery, which will be described in detail. The boilers themselves are four in number, contained in two batteries of two each. They are of the Goldie and McCulloch water tube type, made by the Goldie



Top Left: Pump room looking from heater platform. Wheeler and Worthington feed pumps, and in back ground, Burnham vacuum pumps. Top Right: Recording flow meter dials on left, oil filter, and recording thermometers, pressure gauges and vacuum gauge or large panel. Bottom Left: Basement under pump room, showing steam and exhaust piping, return traps, and flow meters. Bottom Right: View of boiler room, showing boiler fronts, stoker hoppers and traveling weigh lorry. Coal bunker overhead.

and McCulloch Co. Galt, Ont., and each boiler is equipped with a Murphy automatic stoker. operated by a small steam engine situated at the side of number one boiler. The boilers work at 125 lbs. pressure the safety valves being set to blow at 135 lbs. The air for combustion is supplied by natural draught. the chimney being 150 feet above the grate level, and maintaining a vacuum in the furnace of .15 in. to .25 in., according to the way the boiler is being worked.

The boilers are of the double drum type the rated horse power of each being 440 but of course. they can be worked to ratings considerably higher than this if the necessity arises. At the time of our visit, only three of the boilers were on the line, one being down for cleaning. and this is the usual method of working.

On the front of each boiler there is an Ellison differential draught gauge, and in addition there is a Hay's CO_2 recorder for each boiler. The method of mounting this instrument can be seen in the illustration the four instruments being set in the same way on each boiler. In addition to the CO_2 recorders there is a General Electric steam flow meter connected to each boiler, the dials being arranged in pairs at each end of the boiler room, so that the boiler operators can see them from any position on the firing platform.

The damper regulator, which is made by the McDonough Damper Regulator Co. is mounted on the back wall of the boiler room, where it is in a convenient position for examination, and yet not liable to be damaged. The space at the back of the boilers, as can be seen in the illustration, is wide enough to allow the men to move around with ease, and it will be noted that the boilers are set high enough to keep the blow off valves well clear of the ground. The illustration shows one half of the blow off valves, the photograph being taken from the passage dividing the two batteries of boilers. There is a Goldie and McCulloch blow down valve next to the boiler, and a "Yarway" sleeve type valve on the outside on each blow down pipe. There are two pipes on each mud drum.

Each boiler is fitted with the Diamond Valve-in Head soot blower, the arrangement of the units being plainly seen in the illustration. Steam for these units is taken from the end of the equalising pipe connecting the drums on each boiler, thus ensuring practically dry steam.

The steam connection from the boilers to the main header, are made through large expansion bends, in the usual way. The boiler tops are reached by a substantial iron ladder at either end of the boiler room. There is ample space in front of the boilers, as can be seen in the photograph. The Ellison draught gauges can be seen on the boiler fronts just above the furnace door.

The Coal and Ash Equipment

There is a complete conveyor equipment for handling the coal and ash, installed by the Canadian Link-Belt Co. There is no handling of the fuel from the time it reaches the yard, until the remaining refuse leaves the yard in the form of ash. This means that the conveyor equipment receives the coal, elevates it to the storage bunker,

View on top flight of coal conveyor above bunker

weighs it before delivering to the stoker hoppers, and picks up the ash from the ashpits, taking it to an ash bunker where it is stored until the car or waggon is ready to take it away. The main unit of the conveyor is known as a Peck Pivoted Bucket Conveyor. It is really an endless chain, on which buckets are fastened at regular intervals in such a manner that they are free to pivot, thus keeping horizontal while travelling up or down the leg at each end, or on the horizontal run of the conveyor. The buckets are 25 inches long by 18 inches wide, while the pitch of the chains is 24 inches. At each joint there is a special chilled roller, 6 inches diameter, which can be seen very plainly in the illustration showing the upper run of the conveyor over the bunker. The rated capacity of the conveyor, when handling coal is 50 tons per hour, but this rate can be exceeded, this particular conveyor having handled seventy tons in seventy minutes, or about 20 per cent. above its rated capacity. Owing to the balance maintained between the buckets moving up and those moving down, there is but little power required, a 7½ h.p. motor being sufficient to operate the conveyor, as shown in the illustration.

The outline drawing shows the general arrangements and sequence of events in handling the coal and ashes. The coal comes into the yard in hopper bottom cars, and is dumped into a receiving hopper right in the track. This hopper has sufficient capacity to take care of the average gondola car. From the hopper it is fed into the crusher, when the coal is of large size, but if the coal is received small enough for stoker purposes the crusher can be bypassed, and the coal fed directly into the Peck conveyor. The crusher is of the two roll type, having 26 inch by 24 inch hard rolls, and is driven by a 15 h.p. motor.

The Peck conveyor picks the coal up from the crusher, and carries it to the overhead bunker. A somewhat unusual condition was present in this installation, which prevented any of the conveyor machinery being placed above ground outside the railway track. The arrangement shown in the drawing was adopted to overcome this. It will be noticed that the chain is carried out past the crusher over two guide sheaves, and back again horizontally to the leg going up outside the boiler room wall.

Coal is unloaded at any point in the overhead bunker by means of a travelling dumper. This is a form of stop, which can be placed at any position on the track required, and causes the buckets to tip up in order to pass over it, thus dumping their contents. As soon as they pass the dumper, they resume their upright position.

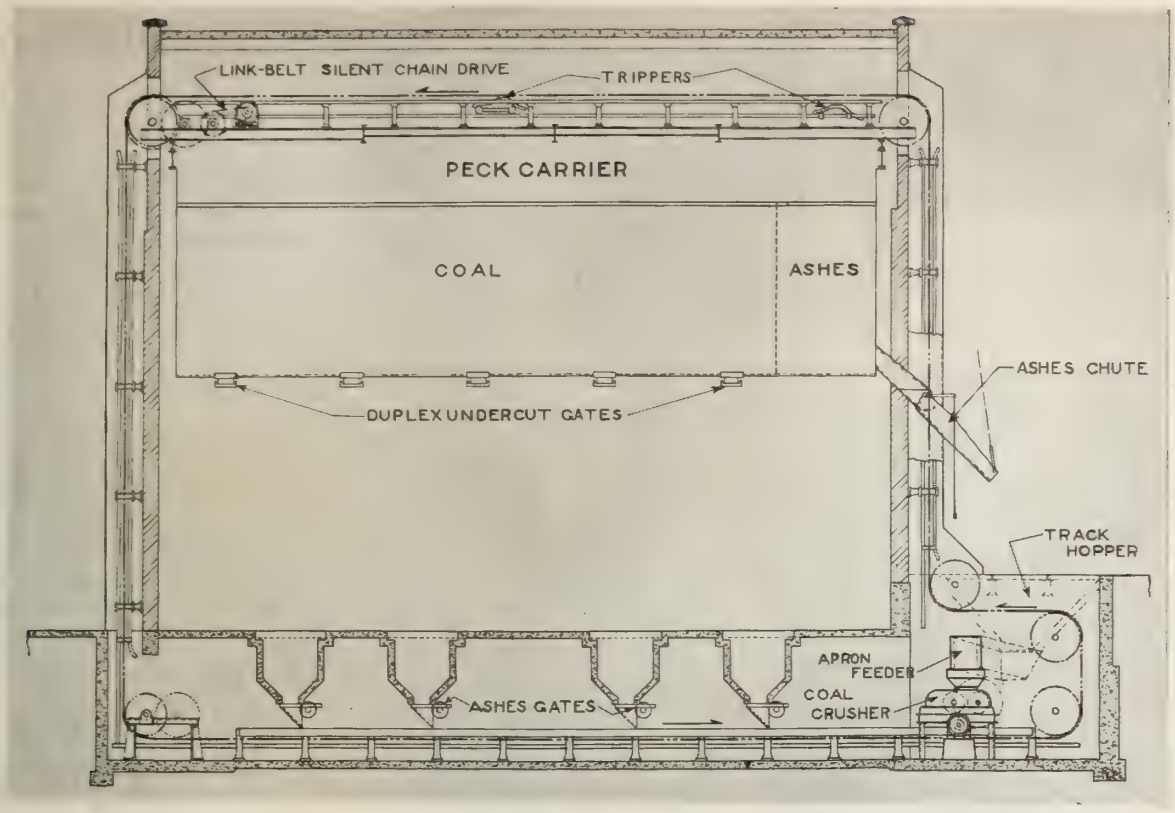
The ash bunker is situated at the far end of the bunker, nearest the wall, and when carying ashes the dumper is of course set at the extreme position. A chute leads from the bunker by means of a travelling larry which weighs the coal, its capacity being 1,500 lbs. The gates on the bottom of the bunker from which the coal is drawn are so arranged that they cannot be opened unless the larry is in position underneath them. This is achieved by building the mechanism for opening the gates into the top of the travelling larry.

The ashes are discharged from the back end of the Murphy stokers into the ashpit which opens into the tunnel, and gates are provided by which the ashes can be picked up at any point by the conveyor. The illustrations convey the general idea very clearly.

The Pump Room

Passing through the dividing door from the boiler room, we find ourselves in the pump room. This room contains the feed and vacuum pumps, and the heater, while the fire pumps are contained in a separate chamber of the main pump room.

The first thing that strikes one's eye, is the arrangement of the heater, and the delicate tracery of the winding stair that looks as though it went up indefinitely. Our photographer was successful in getting an excellent view of this stairway, and the heater, from the floor of the pump room. The reader can form a good idea of the position of the heater with relation to the pumps by noting the top of the air vessel of the nearest pump just showing in the photograph. This stairway was made by



The general arrangement of coal and ash conveyor

the Ornamental Iron Works of the Canadian Allis Chalmers, Toronto, and it is certainly an unusual but very pleasing addition to a power plant. In most cases the need of such a stair would have been filled by a useful, but not ornamental, straight iron ladder. The existing stairway is far easier to climb, and much more attractive to the eye. It leads to the roof, from whence access is obtained to the top flight of the conveyor. The photographer, who had to carry a heavy tripod camera up there to obtain the photograph, also gave his unqualified approval to the spiral stair. both from a physical and aesthetic point of view.

The heater is a Cochrane open heater, supplied by the Allis Chalmers Co., and having a capacity of 60,000 lbs. per hour. It is fitted with a V notch meter for measuring the water passing through it, and this meter can be seen on top of the heater on the right. The tank on the pipe up at the top of the wall is an air eliminating tank, for the returns from the vacuum pump, before they go to the heater. The suction pipe to the feed pumps can be seen at the front, and the exhaust pipe and oil separator entering the heater on the left hand side are also plainly shown. The back pressure valve and atmospheric pipe are seen on the left hand side. In the main pump room there are two feed and two vacuum pumps. The feed pumps are respectively a Worthington 12 x 7 x 12, and a Wheeler 10 x 6 x 12 inches. The vacuum pumps, in connection with the Webster heating system, are 10 x 14 x 16, and 12 x 18 x 20 inches respectively. On the wall behind the pumps can be seen the gauges in connection with the vacuum system, and the connection from the main steam to the heating main through a Foster reducing valve. The by-pass is seen right above the reducing valve. The fire pump room which opens off the main pump room at the south end, contains a centrifugal and reciprocating pump. The centrifugal pump is a Worthington direct connected to a C. G. E. induction motor, and having a capacity of 1,000 gallons per minute against a head of 100 lbs., at 1,440 r.p.m. The reciprocating pump is a Buffalo steam pump, Underwriter pattern, having a capacity of 750 gallons per minute. It is 16 x 9 x 12 inches. This fire pump room does not extend the whole width of the pump room, the remaining space being used for wash room and locker purposes.

The Basement

A corner of the basement is shown in the illustration, the opening at the left being the tunnel in which the steam pipes, etc. going to the factory are carried. On the corner of the wall, on a shelf, can be seen one of the Republic flow meters, of which there are four, connected to various departments to measure their steam consumption. The indicating dials are in the engine room. The steam and exhaust heating mains can be seen on the roof of the ceiling, and the return traps draining these members are seen on the wall. To prove that this is a picture taken under ordinary working conditions there is a little trail of dampness on the floor from some small leak, perhaps.

In the basement, though not shown in the illustration, there is a small centrifugal pump, motor driven, which is used for pumping the water from the water softeners to a soft water storage tank, which is contained in the pump room. One of the principal requirements of this industry is a large supply of pure water, and in order to obtain this, both Refinite and Permutit systems have been installed.

The Engine Room

The engine room is a large square room, filled with light, clean as a new pin, and altogether, about as pleasant a place as an engineer could look for in which to pass his working hours. The walls are all finished in white and glazed enamelled brick, and the floor is tiled. The height can be seen both from the inside and outside views we show, and a very interesting feature is the lighting arrangement, consisting of a regular street lamp fixture, with four arms, and four lamps. This fixture is practically in the centre of the engine room, and although we have not seen it at night, we can well understand that it will prove a very efficient arrangement, especially with the backing of those white walls.

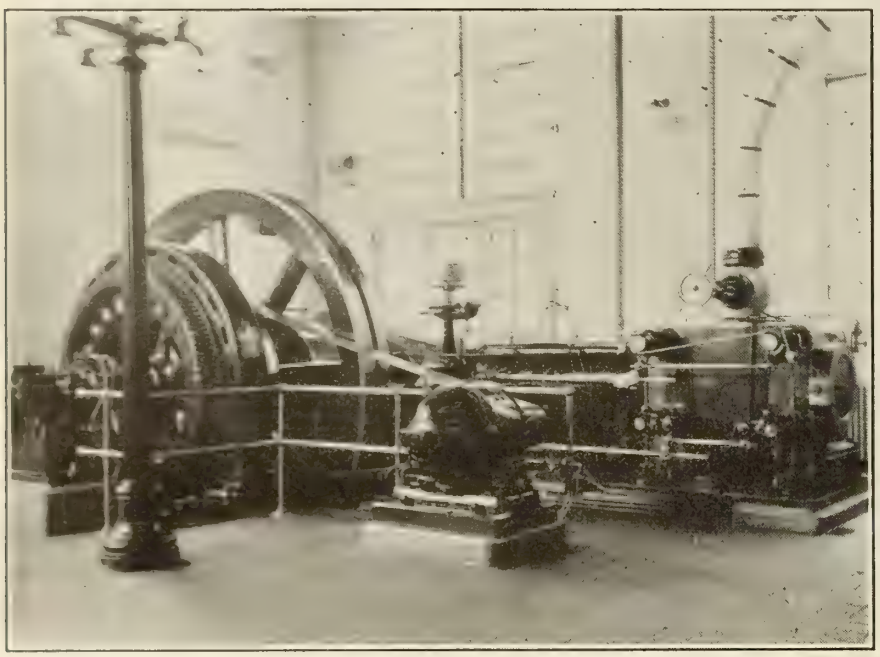
The engine is a Goldie and McCulloch heavy duty Corliss, single cylinder, noncondensing, with a cylinder 22 inches diameter and 36 inch stroke, and 125 lbs. working pressure.

It is direct conected to a Canadian General Electric alternator, developing 375 K.V.A. at 550 volts, and 25 cycles. The exciting unit is driven by belt from the engine by means of a pulley.

The switchboard contains eight panels, and these are divided into receiving and distributing panels for both the

engine and the hydro power. There are four power distributing panels, and two lighting panels, the other two being the receiving panels. The board contains in addition to the instruments for ordinary operation, a recording wattmeter, graphic meter, integrating and recording K. W. meter, and automatic voltage regulator.

The power from engine and hydro is regulated in such a manner that the engine takes all peak leads, thus keeping the hydro demand down to a steady figure, which averages about 600 h.p. The exhaust from the engine is used to supply hot water to the dye house in the summer, and in the winter, in addition to this duty, there is the heating of the buildings to look after. The feed is also heated by exhaust from the engine through the Cochrane heater.



Goldie and McCulloch Corliss direct connected to G. E. alternator 375 K.V.A. 550 volts, 25 cycles

On the engine room wall between the doors leading to the heater platform and pump room, is set the gauge board, oil filter for the engine lubricating oil, and the indicating dials in connection with the Republic flow meters in the basement. The gauge board is a marble panel, matching the switchboard panels, and contains six gauges. These are at the top, a recording thermometer showing feed heater temperature, which averages about 210 degrees. The next two below it are the low and high pressure steam recording gauges, the low pressure on the left and the high on the right. The next lower gauge is the stack temperature recording gauge, which reads 450 degrees. The pair below that are, respectively, on the left the vacuum gauge in connection with the heating system, showing 10 inches, and the city water pressure gauge.

The dials of the flow meters are arranged so that they can be switched to any of four departments taking steam. There are four separate departments from which records are required, and each dial is connected to two instruments, so that by throwing a switch, either of the two instruments with which it is connected will register. The engine carries about 250 h.p. in summer, and in winter, when the lighting load is on, the horse power is about 450.

The Power Staff

We were fortunate in being able to get a group photograph of the staff which operates this plant. Seated in the chairs in the front of the group are the chief engineer, Mr. W. Clark, and the chief electrician Mr. Farrar. Mr. W. Clark, is sitting on the right hand side, with Mr. Farrar, the chief electrician on Mr. Clark's right, or the reader's left.

The group behind, reading from left to right, are Messrs. Lloyd, fireman; Griffiths, assistant engineer, Ransome, repair man; J. Goold, fireman, (who by the way has the Military Medal, won in the Great War); Sellers, and Strain.

The plant is kept in apple pie order, not only in the places which are exposed to the view, but in the corners and basement also. Brass work is shining, and floors are spotless, while the boiler room is remarkably free from dust. The only trace of anything looking like a leak that we saw was that shown in the photo of the basement, and the source of that was not visible. We do not say that there was not a leak in the plant, but there were certainly none that assailed the ear or eye, and we have a pretty keen eye for those kind of things.

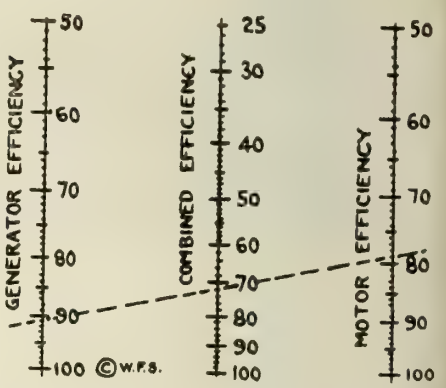
The plant is one of the most interesting in the city, the engine room in particular being one that pleases the eye with its large expanse, and broad high windows. When we think of some of the glory holes we have seen engine and boiler rooms crowded into, we can understand why the staff wear the contented looks shown in the picture.

What is the Combined Efficiency?

By W. F. Schaphorst

In the electrical transmission of power we always have at least two efficiencies to consider—the efficiency of the generator and the efficiency of the motor. Where the distance between generator and motor is great the line efficiency also must be considered, but in most factories and shops using electric power distribution the line efficiency is so nearly 100 per cent. that it can be neglected. I have therefore neglected line efficiency on this little chart.

For example, if the efficiency of the generator is 91 per cent., and motor 79 per cent., the dotted line drawn across this chart shows the combined efficiency to be 72 per cent. The chart will figure



any combination where the efficiency of either generator or motor is over 50 per cent.

One of the much mooted questions is: which is best—electric or belt transmission? The answer is: "It all depends on conditions." The object of this chart, therefore, is to help you answer the question for yourself. With ball bearings and low belt tensions the efficiency of belts and shafts may reach a very high figure—95 per cent. and over. That is a point that must be taken up with the manufacturer. But if it is made certain belt transmission will provide even 80 per cent. efficiency that, in most cases, would eliminate the electric drive, although, of course, efficiency is not the only thing to be considered.

To assist users of the chart I give these average efficiencies of generators and motors at full load: Direct current generators—50 Kw, 90 per cent.; 100 Kw, 91 per cent:; 1,000 Kw, 93 per cent—Motors, ¾ h. p., 64 per cent.; 5 h. p. 80 per cent.; 15 h. p., 84 per cent.; 30 h. p., 90 per cent., 150 h. p., 92 per cent.

Alternating current generators: 50 Kva. 90 per cent.; 100 Kva, 91.5 per cent.; 500 Kva, 94.5 per cent.; 1,000 Kva, and over 95 per cent.—Motors, 1 h. p., 76 per cent.; 10 h. p., 85 per cent.; 100 h. p., 90 per cent.; 200 h. p., 92 per cent.

Economisers and Economiser Operation

Status of the Economiser in American Practice—Where An Economiser Installation is Indicated—Progress in Structural Details—Modifications in Soot Cleaning Arrangements—Notes on the Operating Features

By FRANK H. PROUTY

THE first ecomomiser installation dates back more than 100 years; every year has seen an increase in the number of installations, yet it may be said that (in the United States) the economiser is still in a period of trial and transition, and has never been fully accepted by the American engineering profession.

Old Installations Often Inefficient

Certainly there are a number of economisers throughout the country which positively detract from the overall efficiency, and which it would be cheaper to remove or permanently bypass than maintain in operation. Such results may come from insufficient stack draught, improper proportioning of economiser heating surface to boiler heating surface, feed-water temperature under 100 degs. F.—causing extreme external corrosion and excessive soot caking,—feed-water temperature over 200 deg. F., which may be too close to the breeching temperature for sufficient heat transfer, or the not uncommon failure due to neglect in operation. On the other hand, there are economiser installations which will meet the manufacturers' entire claims, and which are indispensable to high efficiency. Such results are obtained when there is 350 deg. F. difference between entering feed-water temperature and breeching temperature, an induced-draught fan to provide ample draught, a proper relation between boiler heating surface and economiser heating surface, a counter-flow relation between water and gases, and a clean economiser.

Theoretical Need of Economisers

The theoretical need of economisers becomes apparent, for if heat is to be imparted to the boiler throughout the travel of gases over the tubes, the gases must manifestly leave the tubes at an appreciably higher temperature than the steam and water within. If the steam temperature is 375 deg. F. and the gases have an excess temperature of 125 deg., then the resulting stack temperature of 500 deg. may represent a loss of 15 per cent. of the total heat available. A counter-flow type of economiser placed between the feed-pump and the boiler and in this flow of gases will most effectively reduce the gas temperature, the water having a high boiling point, due to its pressure and high heat absorption, because by flowing in a direction opposite to the flow of gases there is always a maximum temperature difference between the two. That counter-flow principle also minimises temperature strains, and with cast-iron tubes and headers this item rises to prominence.

The lower the temperature of the feed-water entering the economiser, the lower will be the final gas temperature, yet the former should never be below 100 deg. F., and preferably well above this figure, because low feed-water temperatures cause moisture in the flue gases to condense on the tubes and headers, and this moisture, combining with the sulphur usually present in the gases, forms sulphuric acid, and rapid corrosion invariably results.

Economisers as Purifiers

Economisers in a limited manner act as purifiers, causing the deposit part of the solid matter held in suspension and precipitating out a large portion of the carbonates held in solution. Most scale is formed by the carbonates and sulphates of magnesium and calcium, the carbonates resulting in temporary hardness and the sulphates in permanent hardness. As only the carbonates are precipitated out in an economiser, it may be said that its purifying action deserves small consideration, it doing little more than relieving the boiler blow-off of carrying away a portion of sludge.

Progress Made in Steel-tube Economisers

Economisers in this country (U.S.) have generally been made cast iron, and because of the tensile weakness of cast iron for high feed-water pressure, numerous attempts have been and are still being made to perfect a steel-tube economiser. Steel-tube economisers have proved unsuccessful in the past because of excessive internal corrosion due to air held in solution with the feed-water. Attempts to galvanize and otherwise coats the inside of steel tubes failed to prevent corrosion. However, recent experiments have shown that the air in feed-water may be greatly reduced by maintaining a heater temperature near the boiling point, by filtering, or by forcing preliminary oxidation by passing the feed-water over iron filings placed in the heater outlet. An improved method now being commercialized is to boil the water under a partial vacuum. This method not only gives an increased extraction of air, but has the additional advantage of treating water with a temperature well under the atmospheric boiling point. This latter point particularly benefits where the temperature of gases flowing through the economiser requires that for maximum heat extraction the feed-water temperature be down around 150 deg. F. A number of steel-tube economisers are now under trial, and with the present development of de-aeration some installations will undoubtedly prove successful. Cast-iron economisers are also subject to internal corrosion, but so moderately that in very few cases has internal corrosion caused failure.

Replacing Mechanical Scrapers by Soot Blowers

Economiser tubes collect an external deposit which requires constant removal and some economisers are equipped with mechanical scrapers for removing this deposit. There is a considerable amount of mechanism to these scrapers, and in recent years a strong movement has been made to replace them by soot blowers. Soot blowers require less exposure of the attendant to the excessive radiant heat of the economiser, they can keep the economiser tubes cleaner, have a lower initial cost, and can be operated and maintained at a considerably less cost than can mechanical scrapers. However, mechanical scrapers will successfully do their work, and they have advantages in that they deposit the scrapings into the hopper underneath the economiser, while the soot blower blows most of the cleanings out of the stack, and the scrapers operate dry, while the soot blowers deposit a certain amount of moisture on the tubes. The latter advantage is of small importance where the water entering the economiser is close to 200 deg. F.; and where superheated steam is used to blow, the use of soot blowers may cause rapid and disastrous corrosion of the economiser. Some manufacturers equip their economisers with soot blowers, while in other instances scrapers have been replaced by soot blowers after the original installation.

Induced-draught Fan Necessary

It may be said, almost without exception, that good results will not be obtained from an economiser unless it is used in conjunction with an induced-draught fan. The loss of draught gas due to gases cooled to around 350 deg. F., together with the additional resistance necessary to pull the gases through the economiser, would require a stack prohibitive in size to carry peak loads or run high ratings.

The commonly used induced-draught fan and short stack result in the emission of large quantities of dust, the

controlling of which gives rise to a problem of considerable magnitude. This dust has been successfully controlled by an induced-draught fan, which also embodies a centrifugal dust-catcher, the dust being driven by centrifugal force to the outside periphery of the fan, where it is deposited and collected. This method removes but a portion of the total dust, and the upkeep cost is largely due to the abrasive action of the particles. Another method is to wash the dust out of the gases by passing them through washers. This method is expensive to install, and a loss occurs in stack draught due to a cooling of the gases. The cheapest and simplest remedy seems to be that of attaching a collecting hopper to the boiler breeching, and baffling the gases down against a series of louvre blades placed in the top of the hopper. These blades snub the dust particles and cause them to drop into the hopper below. As this dust often contains from 60 to 65 per cent. fixed carbon it is possible to burn it in a Coxe stoker.

Economiser Operation

Cast-iron economiser tubes are usually cleaned with water-driven turbines, the water acting as a cushion and preventing the turbine from smashing the tubes. However, an air-driven turbine can be used with equal success if equipped with a limit ring. After cleaning economisers several times it is often difficult to prevent the caps from leaking. In such cases hot joint paste is superior to pastes of lead or shellac.

When economisers are newly installed it is not unusual to experience a considerable breakage of headers. The cause may be initial strains in sections set up when section is assembled at factory, pressure shock in feed-water lines, temperature shock due to cold air coming up through openings in hopper under economiser, or by expansion strains due to local conditions. When a factory-assembled header breaks and it is replaced by a hand-assembled header, the latter seldom breaks. In order to avoid pressure shocks, every economiser installation should have an air chamber in the feed line. This chamber may consist simply of a dead-end pipe connected to the feed-line and carried well up above the economiser.

Manufacturers of economisers once advised by-pass flues for by-passing the gases around the economiser when repairs are being made. It has been found that generally there is not enough use for a by-pass to warrant its existence, and when once installed a by-pass is a constant annoyance, due to leaks and damper disarrangement. If the induced-draught fans are to be worked by automatic control, it is advisable to place a damper in the economiser breeching. This damper, if properly tied in with the fan, will assist the fan in finding its proper draught balance.

Economisers Not Always Installed in Modern Plants

As previously stated, economisers have never been fully accepted by the American engineering profession, and many modern plants are being built with economisers permanently omitted. However, most of these plants, instead of truly eliminating the economiser, have really made it an integral part of the boiler itself. The most common method employed when economisers are omitted on horizontal-tube boilers is to build the boiler several rows of tubes higher than standard, and this additional heating surface really amounts to an integral steel-tube economiser. With vertical-tube boilers the additional tubes are added to the rear tubes of the boiler. One advantage of this method is that the increased resistance to gas flow is so small that an induced-draught fan is not required, and by insulating the breeching and lining the stack it is possible to run high ratings on stack draught without induced draught fans. Of course, it is always possible to get lower final stack temperatures by using an economiser, and hence higher overall efficiency, but it is a much mooted question whether the net financial gain will always favour the installation of economisers. If it is decided to install economisers in a modern boiler-house, a heat balance should be worked up very carefully to determine whether auxiliaries shall be steam or motor driven. It is usually necessary to motor drive some of the auxiliaries in order to avoid an excess of exhaust steam in the heater such as would raise the feed-water temperature above the most economical temperature for economiser operation.—"The Blast Furnace and Steel Plant," Pittsburgh, U. S. A.

HEATING AND VENTILATING ENGINEERS

A Canadian Chapter has been formed of the American Association of Heating and Ventilating Engineers, to be known as the "Canadian Division, Ontario Chapter," with a membership of about 35. The first meeting was held on June 2nd and the following officers appointed:

M. F. Thomas, president; H. H. Angus, vice-president; A. S. Leitch, secretary; A. J. Dickey, treasurer.

Monthly meetings will be held in Toronto.

OXYGEN PRODUCERS CONSOLIDATE

The consolidation recently of the manufacturing and distributing resources of the Dominion Oxygen Company, Limited, and the National Electro Products, Limited, gives to Canada one of the largest organizations of its kind on the continent. The business is henceforth to be conducted under the name of the Dominion Oxygen Company, Limited, now operating oxygen plants at Montreal and Toronto, and acetylene plants at Merriton, Winnipeg and Shawinigan Falls. In addition the company conducts oxygen and acetylene distributing stations at Hamilton, Windsor and Quebec. It is claimed that the union of the two companies will be of material advantage to all Canadian oxygen users through stabilization of the product, assurance of steady supply and certain improvements in service that enlarged facilities will make possible. It is understood that Mr. W. J. Cluff and associates, of Toronto and Montreal, who founded the National Electro Products, Limited, several years ago, will retain their relationship with the oxygen industry through their interest in the consolidated companies.

U. S. BUREAU OF MINES

O. P. Hood, chief mechanical engineer of the Bureau of Mines, sailed on July 12 for London. Mr. Hood will spend three months in Europe studying new developments in lignite utilization and the low temperature carbonization of coal, for the purpose of applying the information to studies in lignite and fuel utilization now being conducted under his direction in the United States by the Bureau of Mines. Mr. Hood will visit England, Germany, Switzerland, Belgium, Holland, Jugo-Slavia, Czecho-Slovakia, Austria, Italy and France.

FIGHTING FOR A CONTRACT

In the consideration of tenders for a four million gallon centrifugal pump for the Toronto Island pumping station, Commissioner Harris, before Toronto Board of Control, was disinclined to award the contract to the John Inglis Co., Toronto, claiming that they were not equipped. He seemed to have lost sight of the fact that the Inglis people have installed pumps to the capacity of two hundred millions of gallons in Toronto services. They have put in a tender of $10,791, which, after some show of a fight in the Board, was accepted. The Toronto plants having Inglis equipment are the main station, twenty million gallons, electrically driven; filtration plant, seventy-five million gallons, steam; sewage plant, twenty, seven, and one and one-half million gallons, electric; main station, fifteen million gallons. Corliss steam; high level, six million gallons, Corliss steam; filtration plant, two million gallons, duplex steam.

"It's pretty tough when a Toronto man can't get a job in his own city," Mr. Inglis told the Board.

"The other pump is a better pump, that's all," remarked Commissioner Harris.

"That makes it a serious matter when the Toronto firm says it will build a pump according to your specifications and with a guarantee," said the mayor.

"What's the use of calling for tenders?" asked another controller, who moved that the local firm get the contract. The motion was carried four to one.

Autobiography of a Sixty-Four-Year-Old Engine

Born in 1858, Nine Years Before Birth of Dominion—Product of Dumfries Foundry—Cylinders Rebored Only Once in That Time —Still Going Strong With Chas. Barber & Sons, Meaford— Vertical Slide Valve Type—Has Passed Through Stirring Times

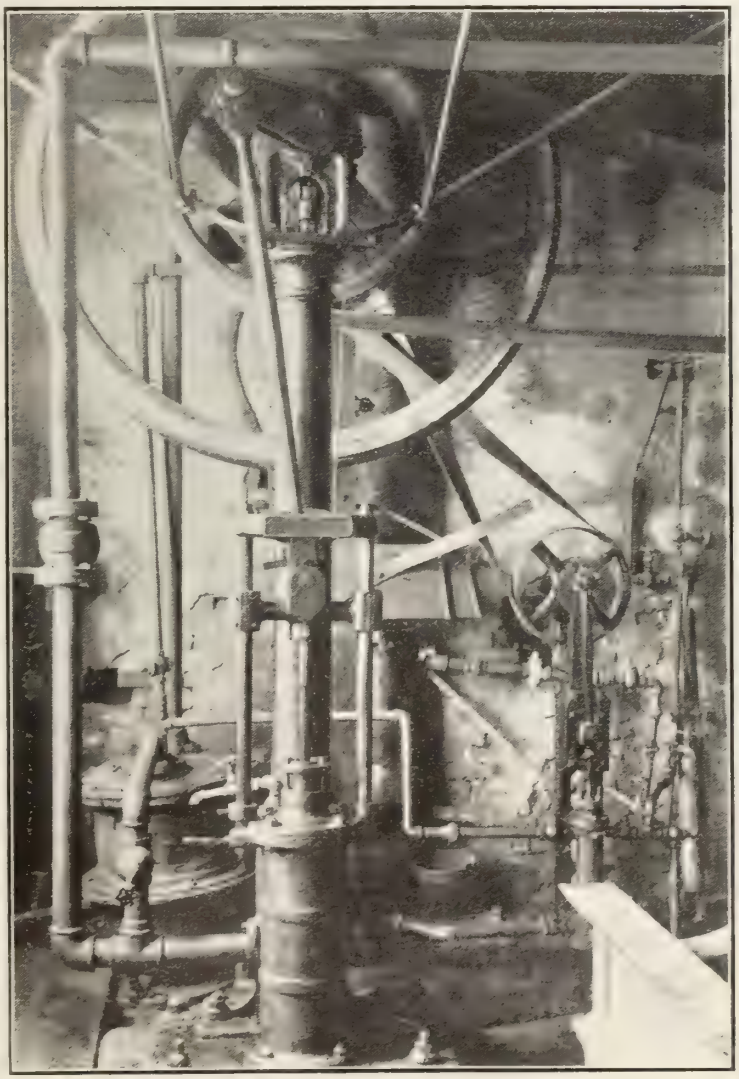
IT HAS often occurred to me that in any autobiography that I might be guilty of, it would be a difficult matter to establish certain matters pertaining to my birth. It seems reasonable to say that certain of the materials entering into my composition were originally in the shape of iron pigs, the ore from which came from a place I have often heard referred to as "the other side." Perhaps they brought my steel from the same place, but the fact that I wish to remember is that the castings, the pistons, the driving rods, and all that were turned out and assembled by the men of the Dumfries Foundry Co., in Galt in 1858. I understand that the firm has since changed its name to the Goldie & McCulloch Co.

It seems absurd that a steam engine such as I am should claim to be a member of any particular sex. If I were a female person, does it not seem ridiculous that I should boast about my 64 years of age? Moreover, in that time I have heard so many names applied to me that I confess I am a bit confused. I recall that, when they had me crated and ready for shipment, one of the men came up to me with a brush and pot of glue and asked some person where "this bird" was going. The reply was that I was going to a village called Leith, near Meaford, and that it was a mighty good place to go. Let me whisper that my first job at turning the wheels of industry was in a brewery. But they fed me on steam from water, and, in spite of my surroundings, I never missed a stroke. Well, an engine must age quickly, in appearance, for I hadn't been on the job very long before the engineer referred to me as an "old girl." I took this in good part, but imagine my consternation when one day about 10 years ago a party of men looked me over and one of them referred to me as "some baby," while it wasn't so long after, that some youth with no germ of reverence in his soul, called me an "old coffee grinder." I think it was the boss who replied that "if you have done your work as well as she has by the time you are 60 years of age, you will not have to view the future with alarm." I thought that was rather fine, and I certainly delivered the goods that day, but there again he seemed to classify me as feminine.

So I have concluded that the sex of the steam engine, like that of a mud turtle or a concrete mixer, is largely a figure of speech. I just wanted to say that I have been wedded to work all of my life, that I feel fit as a fiddle yet, and if I couldn't do a good day's work I wouldn't want to be here.

To return to the story. A few years later, something happened and I was moved to the machine shop of Chas. Barber at Meaford. Call it the irony of fate, or just engine luck, whatever you like, but to come from a brewery to a place where they were making water turbines seemed quite a radical change. However, I had always been noted for my sobriety, and I understand that at the present time the national drink is water and quite a few places that once were breweries are specializing in what are known as kickless libations. I have often wondered how an engine would behave if given a shot or two of "double distilled damnation." I overheard a man remark once that he had had a few shots and felt all "gummed up;" so I supposed that would be my experience. Nothing, not even a human being, can do a good day's work as a regular thing, on gummed cylinders. Believe me or not, just as you like, but I should know what I am talking about when I say that in all my 64 years' experience. I have only had my cylinders rebored once, and that is the only time I was ever shut down for any length of time. That, I should say, is a record. I suppose there are those who will say that had I been fed on alcoholic substance, my cylinders would have given out long ago. All I have to say is, it depends on the cylinders.

During my lifetime, a lot has happened to Canada. I had just taken on my first job at a time when there was some kind of row between Upper and Lower Canada over representation by population. In those days Upper Can-



Steam engine built by Dumfries Foundry Co., Galt, sixty-four years ago. Still in operation in plant of Chas. Barber & Sons, Meaford.

ada had about one million and a quarter of population while lower Canada or Quebec had about one million. Galt, I may say had about 5,000.

Things at that time were shaping towards Confederation and I was some engine on that 1st of July, 1867, our first Dominion Day. I remember the American Civil War, which Canadians helped to win, and also that first of June in 1866 when the Fenians crossed over at Black Rock near Buffalo and threatened to clean up Canada. However, I still plugged away, and was pleased to learn shortly afterwards that the Fenians had returned home, not without losses, and that these unfriendly acts were stopped.

Among other events of an unpleasant nature that have occurred in my day was the Red River rebellion in 1869, when Louis Riel, and some French and half-breeds on the Red River, resented the action of the government in taking over the Northwest. This trouble was crushed, and the country settled down to business. I want you to know that I was shaking a pretty mean piston when Winnipeg, then Fort Garry, was in the making. I was in fine shape during the building of the Intercolonial and the Canadian Pacific railways, and have passed through all kinds of those political crises which seem necessary in the building of a young country, and it is some source of satisfaction that the country and I have come through it unscathed and still have a future. I think it was during a political campaign that I was bored for the second time in my existence.

The Northwest rebellion came along in 1885, and was short-lived, as was also Louis Riel, once they nabbed him. Then, fourteen years later, occurred the South African war, and Meaford sent some of her boys in the first contingent to aid the Motherland. Maybe I didn't regret that I was only a steam engine in those days, but I did the next best thing and kicked out a good day's work at home. Then, in 1901, the whole country mourned the death of Queen Victoria. It was not long after this that the Duke of Cornwall and York visited Canada.

You must remember that during all of these years, Canada has been growing by leaps and bounds, not only in population, but in development of resources. When I was but a kid, they still illuminated the streets with coal oil lamps, and the houses to. Horses were used for Toronto street cars. If a person wanted to go anywhere he probably went on horseback. It took three or four hours to drive over to Owen Sound, and here I want to say that I hope I'll live to see the day when there will be some kind of railroad running over to that town. To drive that distance in winter time is no joke. Well, now we have gas and electricity and these have brought about great changes in methods of doing things. To add to the pep of the times, along came the motor car, and the internal combustion engine and aeroplanes, all that sort of thing. Speed and increased production have supplanted the methods of saddle days. I want to claim a certain amount of credit, for I have had some share in it all, having helped turn out equipment used to generate electricity. Interesting, is it not, to think that an engine of my age should be identified actively in a modern engineering plant?

The most tremendous event of my career was the world war. This was a gigantic struggle, and early in the game I could see that it was going to demand the best in all of us. We were pushed to the limit, but again came through victorious. The fact I want to press home here is that a lot of things, some big and some little, some good and some bad, can happen in the course of sixty-four years, but if you are made of the right stuff, stick to business and measure up to its demands, you are bound to come through. Take it from one who knows more about revolutions than Ireland or Mexico put together, the man or engine who minds his own business, and does it well, won't have time to get into trouble.

There goes the whistle, and I guess they'll choke me off for the night. Take a look at my picture. I'm of the vertical, slide valve type, and differ somewhat from my more graceful, modern brothers or sisters. But though I may be odd looking, I know something about "the amplitude of time," and don't owe anybody anything.

NOTES ON SPONTANEOUS COMBUSTION

Although coal may be a wee bit difficult to obtain and store at the present moment, the Bureau of Mines evidently is of the opinion that some day the black diamonds will again be tumbling merrily into hopper and bin, from a statement just made by O. P. Hood, chief mechanical engineer, on the storage of coal and the attendant problem of spontaneous heating. In storing coal, the risk per ton of spontaneous combustion is really very small, says Mr. Hood. If one counted the times a portion of coal was stored where it would be undisturbed for a few weeks, the number of storage operations in any one year would mount into the millions. Of these, a relatively small number show the phenomena of spontaneous combustion. It is extremely rare that in the smaller operations involving only a few tons there is any heating. There is spontaneous combustion of anthracite, and very rarely does the domestic consumer of bituminous coal find troublesome heating. The main interest in the subject lies in the large piles needed as reserves for public-service utilities and the industries.

Everyone desires to have directions for storage that are perfectly simple and yet will insure against loss. Unfortunately, the problem is too complicated for a simple solution. Many of the factors involved are difficult to determine, as there are no practical means of quantitative measurement. The factors involve chemistry, physics, and engineering, and the man who is in close contact with the problem of stored coal is not always a good observer in these several lines. The result is many incorrect theories, opinions, and prejudices. Much has been written on the subject, and the Bureau of Mines has published the results of extensive investigations, but the diversity of widely held opinions shows that there is need of pointing out what are the factors that demonstrably are most concerned in the spontaneous heating of coal.

Acre of Exposed Surface in Ton of Fine Coal

The heating of coal is believed to be a surface phenomenon. If a ton of bituminous coal could be delivered in a single cube, each dimension of the cube would be about 2.8 feet. When coal heats, it is due to something that goes on with respect to the surface and not something that happens inside of the piece. So far as is known, this is true no matter how finely the piece is divided. It is, therefore, interesting to know the area of the total exposed surface in a ton of coal. If the cube, having originally an area of about 47 square feet, be continuously subdivided until all the pieces are fine enough just to pass through a 16-mesh screen the area of exposed surface in one ton of coal becomes an acre. It is perfectly obvious from this why it is that trouble from spontaneous combustion originates in fine coal, because the great increase in extent of surface does not begin until one gets below 1¼ inch, or nut size. If fine coal is kept out of the pile the heating surface is relatively so small as to remove the cause of spontaneous combustion. This remark applies not to the fact that one may buy lump coal but to the size of what actually gets into the storage pile. Coal bought as lump at the mine and handled with modern disregard for breakage may be far from lump coal when in the pile.

A unit of area of this coal surface generates a certain amount of heat, provided the coal can find the combining material, that is, oxygen. The amount of heat generated depends upon the temperature of a piece of coal. That is to say, coal put into storage at a temperature of 80° F. will generate very much more heat per unit of surface than if put into storage at the temperature of 60° F. It has already been a matter of observation that coal stored during the hot months of summer and in heated regions is much more liable to spontaneous combustion than coal stored in colder climes and in cooler seasons of the year.

Another most important factor is the freshness of the broken coal surface. For the first few days or weeks the freshly broken coal surface is very much more active in the taking up of oxygen and consequent production of heat than after a few weeks or months—a fact that must be borne in mind when considering the wisdom of crushing coal immediately before storing it. Spontaneous fires rarely occur after the coal surfaces have been exposed for three

months. As the rate of heating increases with the temperature, it is evident that if the heat generated is not removed, the process becomes a self-aggravating one, and the rate of heat generation, instead of falling, may rise with time. If the temperature of the pile reaches 140° or 150° F. and continues to rise, there is a high possibility that within a few weeks a destructive temperature will be reached. If the temperature reaches 160° or 180° F., there is almost certainty that a destructive temperature will be reached and that the coal must be moved. Immediately the question of getting rid of the heat is presented.

A Pile of Coal "Breathes"

A coal pile is cooled by radiation and by the movement of air through it. Air moves rather freely through a pile of coal, and in many piles of coal this natural change, or breathing, of air is enough to carry away the heat generated. Some observers have stated that, in general, fires in large coal piles are found in the regions from 5 to 8 feet below the surface on the flanks of the pile. The rise in temperature of a coal pile is thus intimately connected with a very complicated ventilating problem, and there are no means of observing or measuring these small and wayward ventilating currents. Since there are no means of knowing just what the ventilation is in any given portion of a pile, there is greater hesitancy in advocating ventilating schemes for coal piles, as one is as likely to make trouble as to prevent it, unless extreme and uniform ventilation is assured.

There are many more factors of minor importance, continues Mr. Hood. One of the troubles has been that undue attention has often been given to the minor factors, such as the sulphur or the volatile-matter content of the coal, height of pile, etc., while the main factors, such as initial temperature, breakage in handling, freshness of the coal, and the screening before storage, have been overlooked or minimized.

Various factors in the spontaneous combustion of coal are discussed by Mr. Hood in Technical Paper 311, issued by the Bureau of Mines.

JAPANESE RAILWAY ELECTRIFICATION

A comprehensive plan has been adopted for the electrification of the Japanese Government railroads and a special bureau has been established to carry out the work. The first sections to be electrified will be the Tokaido line, 408 miles, from Tokyo to Kobe, and a portion of the central line between Tokyo and Kofu. It is proposed to supply power from a hydroelectric plant on the Shinano River. Electrification of the seven-mile section now in operation over Usui Pass, between Tokyo and Nagano, has been highly successful, according to Commerce Monthly.

Some of the Factors Entering Into Power Costs

THE manufacturer's cost of power in many cases only amounts to the equivalent of petty cash, and has therefore during prosperous times received very little consideration. However, due to competition, the manufacturer to-day is watching very carefully the items of his petty cash and should in turn take a greater interest in his electric power bill and understand something of the factors which enter into its makeup.

A Canadian manufacturer's bill, generally speaking, is based on one of two methods. 1. A charge of so many cents per kilowatt hours only. 2. A charge per h. p. of demand, plus a charge per kilowatt hour.

Ten years ago, practically the only method in Canada was No. 1, but the power companies came to realize that there was a difference between the customer who used 24 kilowatt hours in one hour and the customer who used 24 kilowatt hours spread over 24 hours. The difference being that the first customer used 24 times the amount of machinery as was required for the second class of customer and in turn the fixed charges would be 24 times as much in the one case as in the other. An illustration with which we are all familiar is the summer hotel. Their rates are always high in view of the service they actually give because they have to pay all the interest charges in a matter of one or two months, instead of spreading it over the whole twelve months as is the case with any hotel in the city.

Now let us consider for a moment what fixed charges represent to a distributor of power. These charges naturally cover the interest on investment on the building of the power station, the construction of canals or reservoirs, the installation of water wheels and generators or steam engines and generators, the building of transmission lines, transformers, etc.

It is an interesting fact that the interest on the building of a water power plant, including the items shown above, represents approximately 85 per cent. of the total cost of supplying the power; in the case of steam, approximately 45 per cent. of supplying the power.

Thus it is readily understood that if one customer requires 24 times the amount of fixed charges for the same number of kilowatt hours, his bill should be greater than the second class of customer mentioned.

The result of the realization by the suppliers of power, of the importance of this factor, led to the second method of charging, i. e. h.p. of demand plus kilowatt hours used. The only real difficulty was there was no instrument at a reasonable price available for the measuring of this factor. Therefore except on large customers (where valuable instruments were economically possible) the total h.p. of the machinery installed was adopted as the basis upon which to determine the h.p. of demand and this system which is fairly well known i. e. the "installed capacity" became quite general.

This system however, was not ideal for the folowing reasons. Some manufacturers will put in motors larger than necessary in order to provide for the future. Others have grown so rapidly that they have motors very considerably overloaded. The installed capacity basis penalizes the first class of manufacturer and gives the second class of manufacturer something for nothing.

Another difficulty is that the driving of individual machines is now considered the best practice from an engineering point of view, but if all the individual motors are totalled up, the installed capacity is quite high compared to the actual amount of power taken at any one time. Thus although the manufacturer is adopting the best practice he will again be paying for more than he uses. Also the manufacturer would pay just the same, as far as the demand portion of this bill was concerned, whether he was busy or slack. Whether he had motors running or idle.

As a result of these conditions a very definite demand was created for instruments at a fair price which would measure the demand portion of a bill. Such instruments have been on the market for some considerable time and are coming into very general use and it may be of interest to give some of the characteristics of their operation. Such instruments take the average of the peak for say 10 or 15 minutes and are so arranged that they push a pointer upwards on the scale. If, for instance, the maximum to-day is 10 h.p. averaged over a 10 or 15 minute period, the pointer will read that amount. If next week the average increases for any 10 or 15 minute period to 15 h.p., the pointer will be pushed up and will remain at that point. An illustration of what is meant by the average over a 10 or 15 minute period makes this point quite clear. Your motor car may have reached for a few moments a speed of 35 miles an hour, but the average speed for a period of 15 minutes will be only 20 miles per hour. In electrical terms your motors may pull 35 h.p. for a few seconds, but the average load or demand over a 15 minute period is only 20 h. p. and 20 h.p. is what the bill would be based on for the demand portion.

Refractory as a Factor of Furnace Life

The Capacity of the Furnace for Continuous Operation Under High Ratings Depends Largely on the Quality of the Lining. Modern Tendencies Are Toward the Monolithic Type of Lining

By I. S. PIETERS

IN THE MODERN boiler room the furnace imposes the limitation. How soon the limitation is encountered depends upon how carefully the furnace is designed and the wisdom in the choice of materials comprising it. It is only comparatively recently that the importance of the furnace has been fully appreciated.

It is the furnace that determines the maximum combustion efficiency that can be attained; it decides the economical efficiency that should be maintained. It is the furnace that is usually the first to wear out and so compel a shut down for repairs. It is also the factor that ordinarily determines how "hard" a boiler or a fire can be worked. The more closely boiler room operation is examined the more apparent will it be that the furnace is all-important. A study of conditions immediately shows why this is the case. Further, it explains why of recent years the furnace has come in for the largest amount of attention and the most radical changes.

Perhaps the most prominent tendency during the last few years has been that of operating boilers at higher rates of evaporation. One boiler horsepower is nominally equivalent to 10 sq. ft. of boiler heating surface; when every 10 sq. ft. of heating surface evaporates 34.5 lb. of water per hour, the output is said to be one boiler horsepower. Actually, however, three to five times this amount of water is evaporated for every square foot of heating surface. This means that somewhat more than three to five times the amount of coal must be burned in the furnace to evaporate this larger amount of water. But by working existing equipment many times harder than the nominal, a given investment is made more useful or the money sunk in new apparatus can be reduced. It pays to work apparatus "hard."

Higher combustion rates necessitate radical changes in both the design of the furnace and the materials that go to make it. Larger furnace volumes are required so that the larger quantity of air and gas may mix with that intimacy so necessary for complete combustion. As ignition is largely a matter of time as well as temperature it has become necessary to increase the length of flame travel as well as the space available for mixing air and combustible gases. To accomplish, the height as well as the volume of the furnace has had to be increased.

Because of the larger quantities of coal going into the furnace at these high evaporation rates, the fuel beds are thicker and so offer higher resistance to the flow of air. Higher drafts thus become necessary as well as much larger volumes of air. Mechanical draft is resorted to, therefore, to handle the air and mechanical stokers are used to handle the fuel.

In consequence of these developments the furnace problems that have come about are two-fold. They are those due to higher temperatures on the one hand and those due to mechanical considerations—greater height and greater volume—on the other. Each is closely inter-related to the other. Before discussing the troubles that have come about on account of the higher temperatures and larger furnaces or attempting to explain why they occur or how they may be mitigated and even eliminated altogether for long periods, a thorough understanding of what the furnace walls and interior must accomplish is worth while.

Conditions the Furnace Must Meet

The structure that constitutes the furnace must not only have sufficient strength to support itself at all temperatures that may occur, but it must be capable of supporting whatever loads may be applied to it and whatever stresses may be exerted over the range of temperature that occurs under the most extreme conditions.

Part of the furnace, the inside, must be capable of withstanding for a reasonable length of time the highest temperatures produced in the furnace—namely temperatures between 2,800 and 3,000 deg. F. It must also be capable of standing up under the erosion and attrition of coal, ash and clinker passing along it and adhering to it as well as attack by the fireman's slice bar while he endeavors to break off lumps of clinker and molten ash. The furnace lining must not be chemically active either with the ash and clinker or impurities in the coal (which usually have low fluxing temperatures) otherwise the lining will surely flux and melt. It should have a minimum co-efficient of expansion and contraction and one that remains nearly constant. The material must not be brittle or it will crack on rapid heating; yet it must be tough so as not to be susceptible to abuse. It should not be too porous otherwise it will allow air to flow from the outside to the inside of the furnace; this cool air, of course, lowers the furnace temperature, wastes heat and fuel, may cause damage to the intensely hot boiler heating surfaces, may overtax an already overloaded stack and hasten the spalling of the refractory in the furnace. Lastly, the flow of heat from the inside to the outside should be minimum.

Each of these requirements—refractoriness, physical strength, surface hardness, low expansion and contraction co-efficient, over a wide temperature range, low heat conductivity, imperviousness to air—is of vital importance. These characteristics and requirements differ so widely that no one material can meet them all. Therefore, furnace walls and settings are no longer made up of one material as was once the case but three, four or more materials are used. Each serves an entirely different and distinct purpose; and in this way each material can be chosen specifically for the special condition it must meet.

This, in brief, explains why the furnace of brick or even of two different kinds of brick is rapidly disappearing. It is the reason why the modern furnace with the longest life, lowest upkeep cost and higher thermal efficiency working under the extremely severe conditions of to-day is now invariably composed of three and sometimes four and five different materials.

Typical Furnace Difficulties

Most furnace troubles originate inside the furnace and these, in turn, contribute to, if they do not actually cause those that take place on the outside. Usually the trouble starts at the joints between bricks. Every joint is a weakness and every layer of cement or mortar a possible source of trouble. It is very easy to understand why.

Each brick expands individually according to its individual characteristics and the temperature to which it is subjected. Bricks differ quite widely among themselves in shape, size and ability to stand up under high temperatures; some shrink more than others and some never reach normal size again after heating. Bricks that are not true to size and shape exert a wide thrust against adjacent bricks. Bricks that are too hard are often brittle and crack with sudden temperature changes, on account of internal pressures due to unequal heating or external pressures.

Consequently, the interior surface of the furnace lining when of brick may be smooth and have all bricks flush when first placed into service but it soon assumes a rough and ragged surface to the fire as the individual bricks work about and so retire from and others tend to protrude into the furnace chamber. Those bricks that are most exposed to the intense heat are the first to melt at the corners and edges. As they wear down, other bricks gradually protrude and these too melt so that an endless cycle of deterioration continually goes on.

The cement used to hold the bricks together is a source of trouble in the majority of furnaces using brick. It is an important factor in determining the

strength of a wall as well as the thermal efficiency of the furnace and its life.

The layer of cement must necessarily be very thin—the thinner the better. On cooling after being heated, it usually shrinks and hardens. This weakens the joint, of course and leaves voids of air where the cement was originally. As the bricks move on expanding and contracting, more cement is forced out from between the joints while some of it melts so that the bricks settle down and many of them become loose while others jam. One commonly finds bricks that can be lifted right out of the wall. It can readily be seen why the brick work under these conditions is short-lived when the fireman roughly tries to dislodge adhering clinker from loose and crumbling brickwork. As the bricks disintegrate and the joints between bricks loosen up more and more air tends to enter the furnace from the outside and the greater becomes the waste of fuel from excess air.

Troubles with brick furnaces can be reduced, of course, by using only brick that is true to size and shape and that run uniformly as to material. Further, the cement must be chosen so that it does not act as a flux for the brick and so that it has as close as possible the same co-efficient of expansion and contraction as the bricks it is to hold together. The great difficulty with brick is, however, that bricks in one consignment will vary among themselves. It is difficult to keep sizes uniform; the clay used may come from different locations; the heat treatment may differ so that some of the bricks are more porous, more brittle and of lower strength than others. Bricks in the same consignment may have been collected from different batches that passed through different ovens so that while nominally the same brick they may have quite different characteristics. There are so many opportunities for differences to creep in. And every difference in treatment and manufacture means a possible source of trouble.

At best brickwork is patchwork where not only the brick but the cement that binds them and the men that lay them are variable factors. The periodic cooling and heating to which the bricks are subjected in service soon show the results. As a furnace may require from several hundred to many thousand bricks it is obvious that the opportunity for trouble is very great.

Troubles, frequent repairs, comparatively short life and high upkeep cost are inherent to the brick setting and the only scientific way to overcome them is to employ a one-piece or monolithic furnace lining.

Meeting the Furnace Problem

Since experience as well as theory show that the joints are the weakest parts of the entire brick lining and also the chief cause of trouble, it can be immediately seen that if the joints can be eliminated an immense stride has been taken toward doing away with furnace troubles. The elimination of joints almost entirely is at once probably the most radical step toward longer furnace life and the extension of furnace limitations that has taken place in a long time. This explains why the one-piece or monolithic or jointless lining is proving such a success; and why it is being used especially where furnace conditions are severe, where shut downs for replacements must be minimized and where high upkeep costs have become so serious as to compel combative measures to be adopted.

With the monolithic lining there are no joints. There are no bricks. The lining is a one-piece lining of the same material that after the first heat assumes a smooth, tough surface. There are no protruding parts to be exposed to the heat, to form the nucleus for the building up of clinker masses or to melt down and cause trouble and expense. There are no joints to cause weakness, to serve as channels for cold air to enter the furnace; no bricks to loosen and fall out; no cement to fuse and disappear and no unequal expansion and contraction.

The one-piece, jointless lining is monolithic, of homogeneous material with one co-efficient of expansion. Expansion and contraction occur en masse, without unequal strains and without cracks. There is no chemical action between different substances; it all behaves alike for it is all of the same substance. The lining is chosen for its ability to withstand heat and furnace conditions. It is a refractory used as a refractory where the requirements are for a refractory, so that all the troubles that do occur with the brick are absent.

When a one-piece or jointless furnace lining is used, the rest of the furnace may be built up of materials that insulate, that is keep the heat in the furnace, and have the strength to carry whatever load may be applied. Usually the insulating material is placed next to the refractory or heat-resisting material, next to which is the outside brick, used for its strength and as a support and protection for the insulation and refractory. Quite often the outer brick is covered with an impervious paint which excludes air from seeping through the brick. As the jointless furnace lining seals up the whole inside of the furnace, the entry of air through it is prevented, the increase in combustion efficiency due to this type of lining usually resulting in an increase of from 1 to 3 per cent. in carbon dioxide.

The jointless furnace lining by doing away with all the inherent defects of the brick setting has increased the life of the furnace anywhere up to 500 per cent., reducing the cost of upkeep proportionately. It has enabled boilers to operate for more than a year and sometimes two years without shut down for furnace repairs where with brick, a new lining was required several times a year. It has increased combustion efficiency and so lowered the cost of fuel. It has enabled boiler evaporation to be increased economically far beyond the range formerly possible with economy.

In short, the elimination of joints in the furnace by adopting a highly refractory one-piece lining without any joints, has permitted big economies to be brought about and at the same time has extended the limitations of the furnace enormously.

NEW PUBLICATIONS

We have received from the Taylor Stoker Co. a copy of a new booklet just issued by them, describing the rotary ash discharges as fitted to Taylor furnaces. The book is entitled "The Rotary Ash Discharge," and contains a number of illustrations of actual installa ions in large plants, some of them of outstanding interest, such as the Hell Gate station in New York, and the Connors Creek installation of the Detroit Edison Co. Besides these illustrations which are reproductions of photographs, there are several line drawings showing the details of the installation. The subject is an interesting one, and is well presented.

The Link Belt Co. have issued a bulletin describing their new crawler crane which is essentially a gasoline operated swinging jib crane, mounted on a caterpillar wheel base. It is especially interesting for such purposes as the reclaiming of coal from storage, or unloading and placing in storage. The caterpillars are so dimensioned that the weight of the crane which is 22 tons, is carried with a pressure of only 10 lbs. per square inch on the ground. The lifting capacity is 10 tons at 12 foot radius, and 3 tons at 30 feet radius. The crane can travel ¾ mile per hour, and climb a 20 per cent. grade.

The Link Belt Co. have issued Book 444 describing their Power Hoe (improved drag scraper) for use in reclaiming coal from storage, handling ashes from pile to trucks, or for any purpose where large heaps of small material has to be handled.

Bulletin No. 106 of the C. A. Dunham Co., Toronto, deals with reducing pressure valves, vacuum pump governors, and balanced lever valves. Both outside and sectional views of the different apparatus are shown, and each part is described by means of a reference number and index. Full particulars of the different valves and their application are given in the bulletin.

Canadian Ingersoll Rand have issued a bulletin, Form K-310-A, describing vertical and horizontal air receivers, air aftercoolers, and moisture traps. The aftercoolers are shown in both vertical and horizontal arrangements.

Sixty-Four Not Out

IN THE GRAND old game of cricket, when a man carries his bat through the entire innings, the record of his score is followed by the words "not out." The engine built by the Dumfries Foundry Co., now Goldie & McCulloch, in the year 1858, is still in the running, and performing useful work for its owners, after sixty-four years of a strenuous life.

There is something to be proud of in the building of a piece of mechanism that can successfully and consistently carry out the duty for which it was designed over a period which exceeds the working life of the man who built it by many years. When the facilities available for building such an engine in the year 1858 are considered, the achievement is all the more creditable. There is of course the fact to be remembered that those days were the days of the real mechanic, who could achieve results with his hands and hand tools, that the average machinist of to-day could not attempt to reach. The machinist must understand how to set up his machine in the proper way, but after that is done, the accuracy or lack of accuracy is a function of the machine, and not of the operator. It is unfortunately true that with the advent of the accurate machine tool, the decline of the mechanic who was proud of his craftmanship began.

The world must move on, and the mass production made possible by machine tools has been of benefit to the community in general, and we would not see the wheels of progress hampered. We cannot help looking with high regard and a certain amount of sentiment on the men who with little else but the hammer and chisel and file, wrought in such fashion that their work remained after they had passed to wherever it is that good mechanics finally reach.

The U. S. Mine Bureau

THERE are some things in which the United States Government shows a good example to the rest of the world, and one of these is in the mater of disseminating specialized information to particular industries and professions. One of the most useful departments is that of the Bureau of Mines, which is continually conducting investigations on the properties of coal, and its efficient application to industry in its various forms. Almost daily bulletins are issued dealing with the results of these researches, and while a large proportion of them have no direct bearing on the problems that Power House readers are interested in, there are a considerable number of them that are full of interesting information. The United States Government mails these bulletins absolutely free of cost, and purely as a matter of courtesy.

We should like to see our own Government showing as much practical interest in the affairs of the citizens of the Dominion.

The Coal Strike Continues

UP TO THE time of writing, the prospects of a settlement of the strike in the United States coal fields seem remote. The shopmen's strike would seem to be in the neighborhood of a compromise, but nothing definite has yet been achieved. Meanwhile, although the days here are hot and sunny, each succeeding one brings the approach of fall a little closer. Our Government does not seem to think there is any cause for alarm, and is inclined to leave the whole matter to the coal dealers and agents. This, of course, is a very easy view to take, but we should imagine that with the knowledge of what a scarcity of coal in the winter means to this country, they would be well advised to take some more active measures. This is especially the case when there is a certain amount of restlessness evident among the miners in Nova Scotia, and the railway shopmen in this country are also thinking of indulging in the luxury of a trial of strength.

The final result is that the public are likely to be gouged when the cold weather actually arrives. If factories have to buy coal to keep their plants running at an exorbitant price, that means that the cost of the articles they are making will be raised in order to make up the difference. The unfortunate householder who has to buy coal in small quantities, and who cannot possibly do without it, no matter what sacrifices are entailed in the buying, has no choice but to dig into his resources and get what coal he can. He has no one to whom to pass on the cost.

It is nonsense to say that no crisis exists, and that everything will be quite all right, when trains are being suspended all over the United States because there is not enough coal to run them. The time to ensure that Ontario is to get a full supply of coal is now, while navigation is open. When the St. Lawrence is frozen up, and the railways have to contend against weather as well as crippled rolling stock it is hard to get coal even when the supply is plentiful. Here is a chance for a Government to achieve distinction by doing something of a real benefit to the people, but the chances of their doing it are, to say the least, not very hopeful.

Editorials in Brief

This is the time of year for picnics. The Toronto branch of the Canadian Asociation of Stationary Engineers are arranging for theirs to take place on the 19th of August, and hope to see a big crowd. Notice will be sent to members shortly as to time and place.

* * * *

The educational work of the various branches of the C.A.S.E. under the auspices of the Grand Lodge Educational Committee, is going to be something of great value to the members. The work will be started as soon as the hot weather is over, that is, with the first meeting in September of the various branches.

Progress in New Equipment

STEAM SUPERHEATER

The conditions of the modern power plant, especially of the central station type, call for a considerable degree of superheat in the steam supplied. There are very definite savings to be made by the use of superheated steam, which range from 10 to 25 per cent., depending on the type of plant. In the case of the steam turbine, superheat is an absolute necessity, and practically no turbine plants are now installed without this apparatus.

The following description of the modern development in superheating apparatus, is that of the superheater made by The Superheater Co., Ltd., at their factory in Sherbrooke, P. Q., and known by the name "Glesco." This is the type installed in the Hell Gate power plant of the United Electric Light and Power Co., New York.

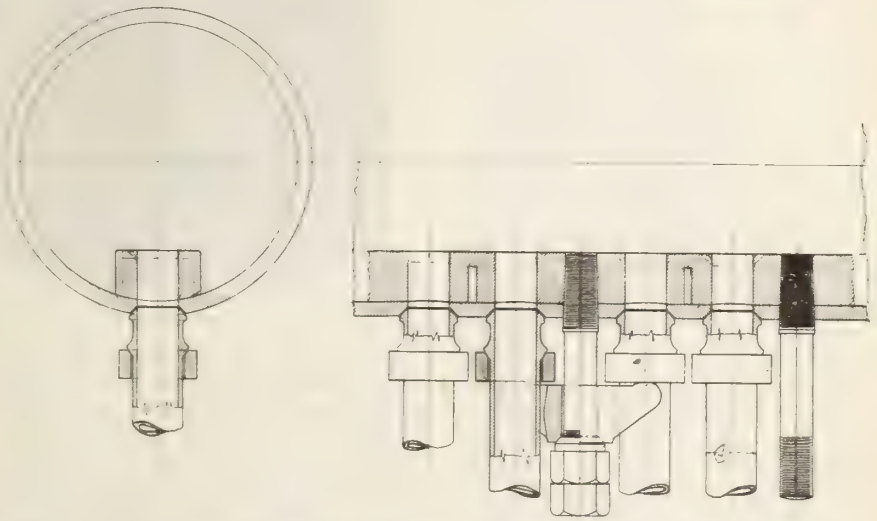

Fig. 1—Detail of Ball Joint Construction between leader and units.

Description

The superheater consists, in general, of two headers, one acting as the distributor for the saturated steam coming from the boiler and the other a collector header for the steam after it has been superheated, and the necessary connecting units in which the actual superheating takes place.

Headers

The headers are made of open hearth steel and are usually located outside of the hot gas path, and in the majority of the designs, outside of the boiler setting proper, so that the headers, as well as unit joints, are accessible for inspection and repairs without entering the boiler setting. The advantage of such an arrangement, particularly under present conditions of labor and supervision, will be readily appreciated. Safety valves conforming to the A.S.M.E. Boiler Code are provided and are located near the outlet. Provision is also made for drainage. Superheated steam headers are provided with thermometer wells.

The headers are made with the outlet on the superheated header in an opposite location to the inlet on the saturated header, assuring an even distribution of the steam flow through all units.

Each header is reinforced along its length with a steel bar milled on one side to fit the interior wall of the header. This detail is shown in Fig. 1. This bar adds the necessary material to provide a sufficient grip for the studs and is drilled along its length at points registering with holes in the header, forming the steam passages between units and header.

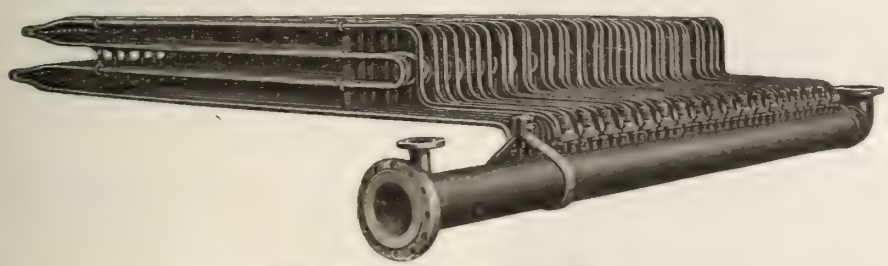

Fig. 2—Superheater for horizontal water tube boiler.

Units are made of heavy cold drawn, seamless steel tubing of the proper diameter to give correct steam areas. The tubing is not covered with any other material and it thus presents a smooth external surface, offers minimum resistance to the flow of the gases and avoids serious collections of soot that would interfere with the efficiency and uniform operation of the superheater. This construction also brings the steam into intimate contact with the gas-touched heating surface, and gives a low resistance to the flow of heat from the gases to the steam.

The form of the unit is such as to permit free expansion and contraction of all parts. The tubes are bent on specially designed machines that do not weaken them or reduce the steam areas. Ample provision is made to prevent the pipes from warping. In cases where severe moisture and scale conditions are prevalent, the units can be made so that they may be satisfactorily cleaned on the in-

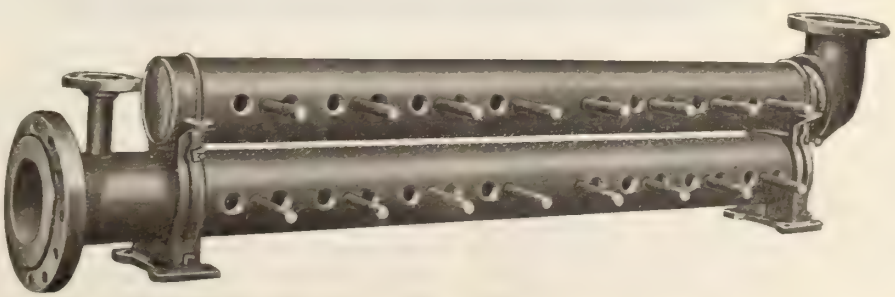

Fig. 3—"Elesco" Superheater ready for application of units.

side. Due to the fact that the units are made of small diameter tubing, it is possible to obtain correct relations between steam areas and heating surface and so distribute the cross sectional area through the superheater as to obtain the most desirable steam velocity without the use of cores. The use of cores in superheater tubes causes a considerable drop in pressure through the superheater, because of the added frictional resistance of the steam and where bad water and foaming occurs, the small space between the cores and the inside of the tubes is quickly stopped by scale-forming material.

The connection between the units and headers is a metal to metal joint. This joint is made so as to permit the easy removal of the units without special tools, and its use also avoids two holes in the header which would be necessary with rolled joints. Any unit in the superheater can be disconnected without interference with the other units, and the work of disconnecting a unit, which consists merely of loosening a bolt, can be done by the ordinary power plant attendant. The ball end, as shown in Fig. 1, is formed integral with the tube by a special forging process. The ball is then faced and ground, and fits into a ground seat in the header, which is made at an angle of 45 degrees. The clamps and washers are made of forged steel, and the header bolts are made of heat-treated alloy steel, with an elastic limit of not less than 75,000 lbs. per square inch. This joint, while a new departure in stationary superheater design, has been used by this company in more than one million five hundred thousand superheater units and is the only metal to metal joint that has withstood the extremely hard service of locomotive operation under steam pressure

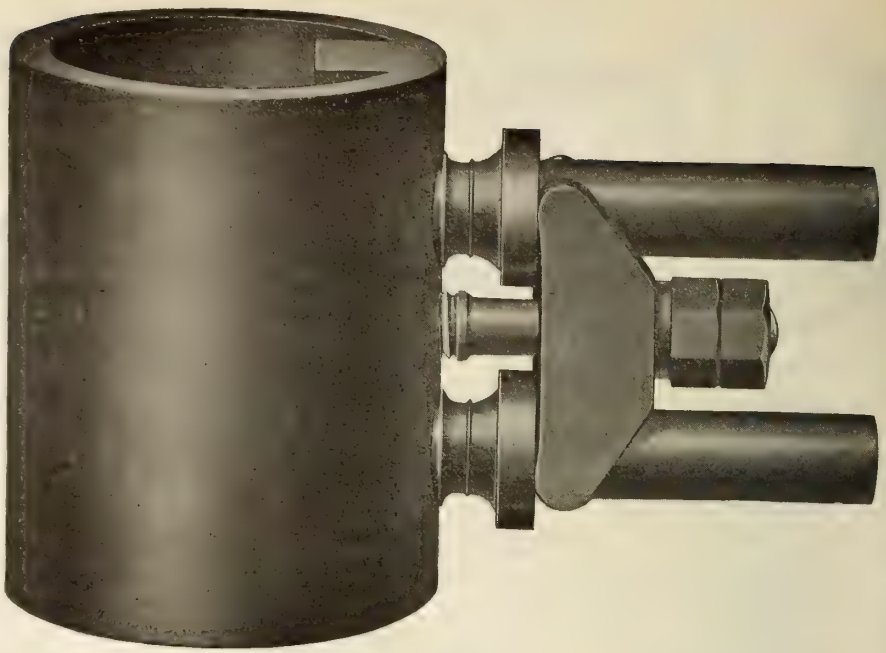

Fig. 4—Section of header and units showing ball joint construction.

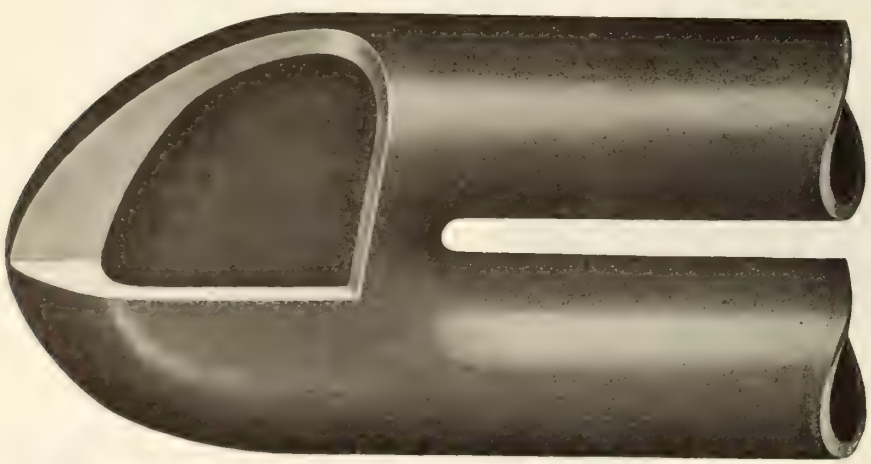

Fig. 5—Forged Return Bend.

of 200 to 225 pounds and total steam temperature of 650 to 750 deg. Fahrenheit.

Return Bends

In most designs of Elesco Superheaters, the loops of the units are forged return bends. These return bends are made on the ends of the units from the metal of the pipe itself by a special mechanical forging process, without the use of electrical or acetylene welding and without the addition of any material or metal. The distribution of the metal as will be seen in Fig. 5 is such that there is an increase at the end. The use of the forged return bend in the unit construction of the Elesco Superheater results in a continuous pipe, the bend being as strong if not stronger than the body of the pipe. It also affords a sharp return without adding excessive pipe friction and facilitates the convenient and advantageous location of the superheater units.

Location of the Superheater

The location of the superheater in all boilers is such that the headers and joints are accessible for inspection and repairs, and so that any unit can be easily withdrawn. In all cases the superheater is entirely separate from the boiler proper, being located in a component part of the boiler setting through which the products of combustion pass, in such a manner that the addition of the superheater increases the over-all efficiency of the boiler by lowering the final flue gas temperature for any given set of furnace conditions. The superheater header is suitably protected from the direct action of the hot gases. Headers and units are securely supported and are independent of the brick work wherever this is possible. No additional care of the boiler is necessary on account of the installation of the superheater, and the design and construction are such as to make the cost of maintenance and operation negligible.

With the ball joint construction, hand holes and gaskets for unit joints are entirely eliminated and the number of joints to be maintained is approximately one-fourth of the number required where rolled joints, including the necessary hand holes, are used.

In case boiler repairs may be necessary, units can be removed and replaced without distorting units or headers and without the destruction of metal in any way. Units can be readily detached, removed or replaced without the need of a boiler maker, it being necessary to remove but two nuts to loosen two units.

High steam velocity is used in Elesco Superheaters, a feature which tends to maintain clean surfaces on the inside of the units.

Units can be blocked off when necessary simply by relieving the pressure on the boiler and applying a dummy coupling to the unit connections.

These superheaters are suitable for application to all types of boilers. They provide maximum superheating efficiency and capacity and maximum combined efficiency of the boiler and superheater, as well as uniformity of superheating effect. Their design and construction is such as to provide freedom from leaks, ease of application and accessibility for inspection and repairs, and maximum length of service without renewal.

PORTABLE ELECTRICAL C. O. 2 & TEMP: INDICATOR

A clever instrument has recently been placed upon the Canadian market for the indication of the percentage of C. O. 2 in flue gases, and by the manipulation of a small switch the flue gas temperature may also be read on the same scale.

The idea is due to Dr. G. A. Shakespeare of Birmingham University, England, the instrument consisting of a galvanometer having two scales, the upper scale being graduated from 0 to 1,000 degrees Fahr., and the lower graduated in percentage of C. O. 2, a Katharometer, i.e., an instrument for indicating the percentage of C. O. 2 in air or the percentage of other similar mixtures, there being no chemical absorbant of the C. O. 2, and a base metal Thermo Couple for flue gas temperatures, and a multiway switch.

The instrument is entirely self contained, put up in a teak carrying case and very portable, weighing fourteen pounds.

The sensitive element consists of two platinum spirals encased in a metal block, the spirals being the fourth arm of a Wheatstone Bridge circuit, and the principle of operation depends upon the difference of temperatures of these two spirals.

One platinum wire is exposed to the gas through three small holes in the end of the metal block. The other is exposed to water which is contained with glass wool in a small brass tube fitted in the bottom of the case, it is only necessary to dampen the glass wool with water, therefore this seldom needs attention.

When the same gas, say pure air surrounds both spirals, the temperatures are the same, and the galvanometer records zero, 0% C. O. 2. When the gas drawn from the flue changes in composition the former wire changes temperature and the indicator pointer is deflected according to the percentage of C. O. 2.

Electric current is supplied to the Bridge by inert cells and provision is made to compensate as the voltage of the cells changes during discharging, the method of compensation is such that the cells do not require renewal for long periods.

Consider four bridge arms two of which are spirals of platinum wire having identical resistance under similar conditions. The other two arms are Manganin wire of equal resistance which is used to complete the bridge. Call the platinum spirals A & B, and the Manganin wires C & D.

If a battery and switch are inserted in this circuit, and the switch closed. a current will flow through the bridge arms.

This will cause heating and change the resistance of the four arms. If conditions are the same around the different arms of the bridge then C & D will lose heat at the same rate, and likewise A & B, consequently, if C & D were equal and A & B were of equal resistance before switch is closed, they will be of equal resistance after.

Therefore the bridge will remain balanced, and the indicator or galvanometer will not be deflected.

Now suppose that the space in the block surrounding the spiral A is filled with a substance that is a better conductor of heat than that around B. Then the heat being conducted away from A faster than from B, will result in A being maintained at a lower temperature and consequently a lower resistance than B. This causes the bridge to be unbalanced, which will be shown by a deflection of the indicator.

The instrument can also be used as a temperature indicator for temperatures up to but not exceeding 1,000 Fahr., without the cells being connected and separate and distinct from C. O. 2 indications, in the manner of an ordinary indicating pyrometer.

This instrument is designed particularly for measuring the percentage of heat going up the stack. For a determination of this it is necessary to know:—

(a) The excess of air; this is given by the C. O. 2.

(b) The rise in temperature of the air from the inlet to the base of the smoke-stack.

The per cent. heat loss can then be calculated from the formula

$$\%\ \text{loss up chimney equals } K.\frac{(t_2 - t_1)}{C}$$

where t1 and t2 are the initial and final temperatures of the gas before and after passing through the fire and economizer.

C equals percentage of C. O. 2 in outlet gases.

K equals a constant depending on the composition of the coal burned.

Any engineer who has used a portable instrument of the chemical reagant type, with caustic potash will easily realize the immense value of the instrument described above, especially to inspecting and consulting engineers.

The manufacture of this instrument is due to the Cambridge & Paul Instrument Co., of Cambridge, England, and has been placed upon the Canadian market by their Canadian branch, Messrs. Instruments Ltd. of Ottawa.

CAST IRON AIR TIGHT DOOR

A new cast iron door, 15″ x 16″, has recently been developed by the Conveyors Corporation of America, Chicago. It is designed especially for boiler settings, and is made air tight to prevent the ingress of air and the leakage of gases.

The door is strong and substantially built, having both frame and door of cast iron. All bearing surfaces are machined to make an air tight contact. Floating hinges pivoted to the door at the center insure an even pressure over the door when it is closed and locked. The door can be provided with either of two types of locks—with a wing nut at the end of a hinge bar, or with a lever locking device which is recommended when the door is subjected to frequent opening and closing.

BOOKLET

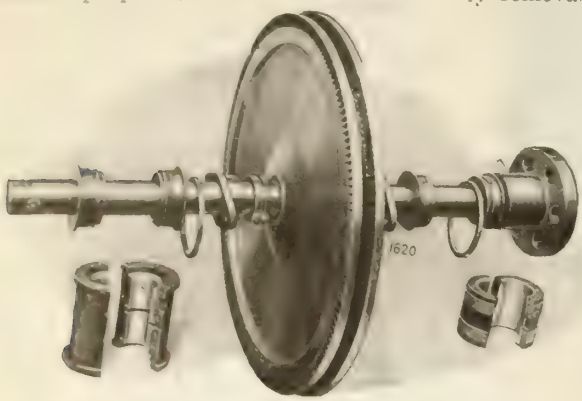
The Automatic Fuel Saving Co. have sent us their booklet describing the Gray system of automatic combustion control. Their representative for Canada is Mr. Chas. N. Green, 825 Chamber of Commerce, Buffalo, New York. The system is a balanced draft arrangement, and the booklet gives full particulars and illustration of the device and its method of installation and operation.

TO MANUFACTURE BABBITT

The Georgian Bay Spring & Babbitt Works, have erected a new factory in Collingwood, Ont., and are preparing to manufacture a high-grade British babbitt. This product will be introduced to the trade as Gray's special No.'s 1, 2, and 3. The company also contemplate the manufacture at an early date of automobile springs.

SMALL STEAM TURBINES

Small steam turbines, as used for driving power plant auxiliaries, such as exciters, circulating pumps, hot well pumps, hurling water air pumps, boiler feed pumps, coal crushers, fans and stokers, etc., ordinarily receive, and should demand, but little attention. They should also be able to use steam at high pressure and superheat, and for their size, should develop the maximum amount of work from the steam, even though the latter is subsequently utilized in feed water heaters or for industrial purposes.



Rotating element and bearings of De Laval velocity stage turbine.

The velocity stage turbine illustrated herewith has been designed to meet these requirements. It is built in sizes up to 1,200 h.p., and can be directly connected to high head centrifugal pumps, blowers and compressors, or by means of speed reducing gears, to medium size alternators and direct current generators, to large centrifugal pumps and blowers, to belt pulleys and rope sheaves, to paper machines, to rolling mills, and to other slow and moderate speed machinery.

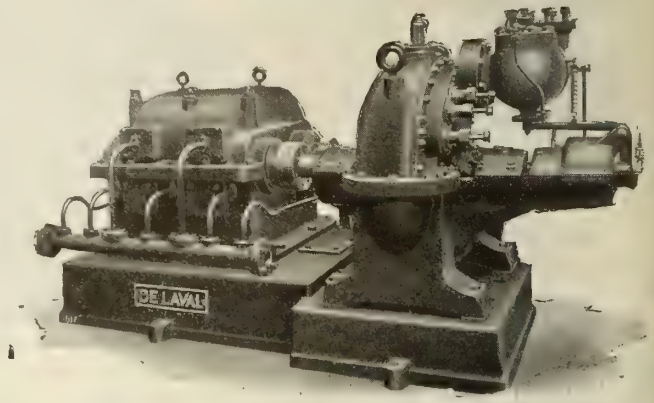
To adapt it for operation with steam of high pressure and superheat, the steam chest and nozzles are located in the casing cover, so that the bearings are not subjected to high temperatures. Since the steam is completely expanded in the nozzles, the turbine case contains steam at exhaust pressure only. For all steam temperatures above 450 deg. F. and for steam pressures above 210 lbs. gage, the steam chest, governor valves, emergency governor valve casing and strainer casing are made of steel.

From the steel steam chest the steam expands through removable nozzles, which are accurately reamed for the ratio of expansion desired. Some of the nozzles are fitted with hand valves so that certain nozzles may be shut off or opened as required by the load or steam conditions, thus permitting the nozzles remaining in service to work at the highest efficiency. The nozzle ring is attached to the steam chest and is easily removable.

The wheel carries two or more rows of buckets, depending upon the speed and steam conditions. The buckets are drop forged from materials best suited to resist the corrosive and erosive action of steam, and are secured to the rim of the wheel by bulb shanks in such a way that individual buckets can be removed without disturbing others. The steam discharged from the first row of buckets passes through guide vanes which direct it upon the succeeding row. These guide vanes are held in removable steel segments attached to the nozzle plates, so that it is a comparatively simple matter to replace them if damaged or worn by long use with wet steam.

The admission of steam to the steam chest is controlled by a speed governor which acts upon a double seated valve. Where the volume of steam to be handled is large, or speed is high or very close speed regulation is desired, the governor is of the Jahns type, mounted on a vertical spindle, which is driven by the turbine shaft through a worm gear. A more simple type of governor, mounted directly upon the turbine shaft, can be used on small and medium sized turbines running at moderate speeds, or where a speed reducing gear is used the governor may be mounted upon the slow speed gear shaft.

The turbine is also equipped with a safety or emergency governor consisting of a small plunger set radially in the shaft and acting against a strong spiral spring. When a predetermined speed is exceeded, this plunger projects

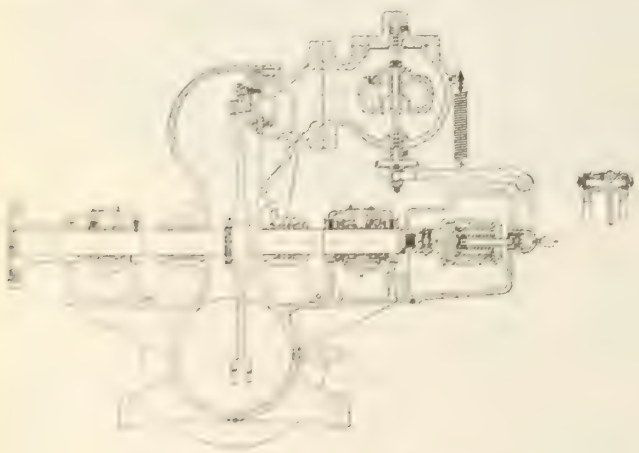


De Laval velocity stage turbine with speed reducing gears; 3,600 to 415 r.p.m., 175 h.p.

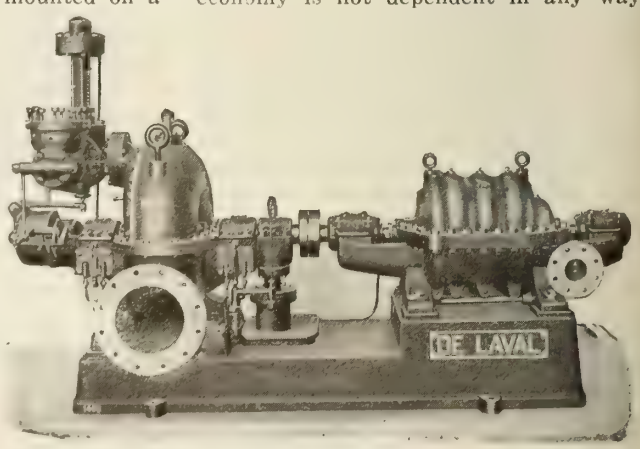
because of centrifugal force and strikes a small lever, tripping a mechanism which immediately closes the emergency valve. This emergency trip or overspeed governor is always mounted on the turbine shaft, and its action is entirely independent of the main speed governor. The valve which is tripped is entirely independent of and separate from the valve used for governing purposes.

The turbine case is divided horizontally so that the top half of it may be removed, giving access to the rotating elements. Upon removing the cover, the rotating parts can be lifted out.

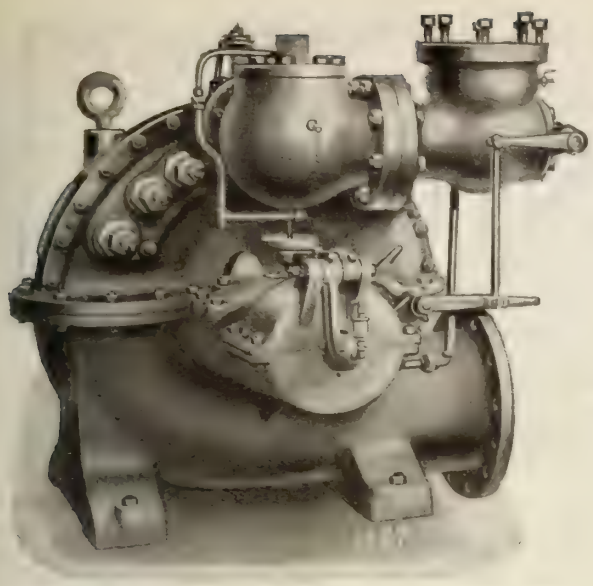
Since the steam is completely expanded in the nozzles, the turbine case contains steam at exhaust pressure only, but an automatic sentinel valve is provided to give warning of excessive pressure in case a valve in the exhaust line be closed. There are no stuffing boxes or packings within the wheel case, and economy is not dependent in any way



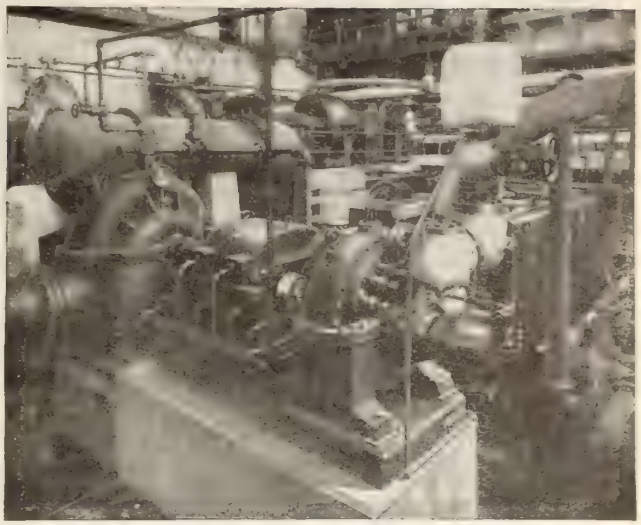
Axial section of De Laval velocity stage turbine.



De Laval velocity stage turbine driving boiler feed pump, 400 gal. per min. against 635 ft. head at 2,500 r.p.m. Turbine fitted with excess pressure governor.



De Laval velocity stage turbine for high pressure temperature steam, showing location of steam chest in casing cover, removed from bearings; also showing the speed governor and valve and the separate shut-off valve controlled by an automatic overspeed trip.



De Laval geared velocity stage turbine driving condenser circulating pump in water works pumping station; 17,500 gal. per min. against 30 ft. head.

upon the maintenance of small clearances. To prevent leakage along the shaft where it penetrates the casing, metallic ring packing is used. For high speed and certain conditions of service, carbon ring packing is employed.

The wheel is a steel forging mounted on the shaft by a taper fit. The shaft is of hammer forged steel, sufficiently short and stiff to put its critical speed far above the running speed.

This turbine is being placed on the market by the De Laval Steam Turbine Company of Trenton, New Jersey, primarily to meet the demand for reliable and efficient auxiliary turbines where high steam pressures and superheats are used. It is, of course, equally satisfactory for less severe steam conditions.

All parts of the turbine are made to limit gages on an interchangeable basis. The system of production control includes skilled engineering supervision, careful purchase and rigid inspection of materials, high quality and accurate workmanship, and complete testing of the finished machines.

STRIKES AND BETTER BUSINESS

Delay in reaching settlements of present labor troubles will temporarily delay expansion, but it will not affect the fundamental causes which for more than a year have been making for better business, declares a New York authority on the situation in the United States.

Conditions at the close of the first half of 1922 indicate that business will expand moderately during the autumn and winter months. It is now one year since the definite beginning of recovery from the depression of 1920-1. Progress was slow until the close of 1921, but since the beginning of 1922 improvement has been rapid. Money is cheap. The crop outlook is excellent. With few exceptions, stocks of raw materials and of manufactured products are not larger than necessary to bridge the normal period between production and consumption. Commodity prices are rising. The movement at present seems to be primarily one of adjustment between the different classes of commodities, and as long as the upward tendency does not assume a speculative character, it is a favorable factor. Except for strikes, there is little idleness. Production has expanded steadily since the beginning of the year, and as yet the usual mid-summer dullness has been little felt.

RURAL POPULATION LEADS

The final figures issued from Ottawa of the sixth census, as of June 1st, gives Canada a population of 8,788,483, an increase of 1,581,840 over 1911 or 21.95 per cent. The census figures show 4,439,505 of the total population residing in rural districts as compared with 4,348,978 living in urban centres. Ontario is leading the way among the Provinces both as to total population and in the number living in the country. Ontario's total population is 2,933,662, of whom 1,226,292 live in rural districts. Quebec is second with a total population of 2,361,199, of whom 1,038,128 reside in the country.

FEAR COMPETITION

According to the proposed rates on machine tools, as framed before Congress at Washington, D. C., the duty on machine tools would be raised to 35 per cent. Should this move go through, it would be the highest rate in force since 1897. In 1909 the rate was 30 per cent., in 1913, 15 per cent., so that the proposed increase is quite drastic. Certain American manufacturers are afraid of German and perhaps British competition, and should the proposed duties go into effect, this competition would automatically cease. Whether the rating goes through is another matter.

Australia has stolen a march on Canada by entering into an agreement with the British Government under the Empire Settlement scheme. Canadian parliament has prorogued without passing the necessary legislation. The plan as proposed will be operative until March, 1923 and will cost £400,000. There will be a grant to desirable immigrants of one-third of cost of passage, another third will be loaned at a low rate of interest, and even the remainder may be advanced if necessary. Initial allowances may also be granted. Australia, owning its own steamers, will make the expenditures and will be refunded one-half by the British Government. Only immigrants proceeding under settlement or development scheme, or assured of other employment in Australia will be eligible for these assisted provisions.

Through lack of power industries at Belleville were completely tied up during the latter part of the week. The situation in Peterboro also threatened, when several factories were compelled to shut down. At the latter place the trouble is said to have been caused by restricting conserved waters, causing a difference in levels, but, on the other hand, the cause is attributed to evaporation. Some difference of opinion seems to exist as to water rental per horsepower and the matter is one that has to be threshed out between the Hydro Commission and Ottawa Government. The Department of Railways and Canals ask a rental of $3.50 per horse power, which is claimed to be exorbitant, and had cut down the supply at hydro stations. As a result industries in several towns are crippled. Formerly, the rates had averaged $1 and $2 and it was claimed that some power concessions in other provinces were securing water from the Dominion free of charge. The Province of Ontario is charging a maximum of 50 cents per horse power.

Management of Direct Current Machinery

By M. BARRY WATSON
Director of Engineering, Toronto Technical Schools.

BADLY developed high bars, flat spots, high mica, low bars or ec centricity of the commutator can only be entirely corrected by turning with tools on a rigid support, or by grinding.

Previous to turning or grinding it is necessary to make sure that the commutator is tight. If not tight make it so by screwing up the clamping ring under the outer end of the bars. Most commutators require to be tightened up after the first six months running and again after a couple of years, after that they should stay tight for life. The examining for looseness and the tightening, if any, should be done immediately after a run while the commutator is still warm.

A commutator may be turned in its own bearings or in an engine lathe. If in its own bearings, it may be driven at reduced speed by belt or otherwise, or it may be run as a motor on normal voltage at reduced speed by putting a resistance in series with the armature circuit.

The tool post should be built up from the frame of the machine, not mounted on the brush holder mountings. In case the machine is being run as a motor, the tool post must be insulated from the frame of the machine and not allowed to come in contact with brush holders, etc. If belt driven the brushes should be removed.

In turning a commutator it is necessary to use a tool with quite a sharp point, but sufficiently rounded that the cuts will overlap and not form a thread, therefore the feed must be very slow. Light cuts must be taken, several cuts being necessary to remove large bad spots or excessive eccentricity. If deep cuts are taken the bars tend to lean over as they are being cut and when they spring back the leading edge will be slightly lower than the trailing edge. If at all possible it is better to remove the armature to a lathe on account of the difficulty of building up a tool post that will be perfectly rigid. The surface speed of the commutator in turning should be about 500 to 600 feet per minute. This surface speed can be calculated as follows:

S = 3.14 x D x N, where S=Surface speed in feet per min. D=Diameter of Commutator in feet, and N=Revolutions per minute.

Before starting to either grind or turn a commutator, the open spaces between the windings should be covered with oilcloth or canvas to prevent chips or dust of copper from lodging in the interstices. This covering must be securely wrapped on to prevent flying off or catching in the tool post or grinder.

Grinding may be done by a stationary stone held firmly in the tool rest or prevent chattering or digging into the commutator, in which case a smooth sand stone similar to a hand stone should be used. The surface speed of the commutator for stationary stone grinding should not usually exceed 1,000 to 1,200 feet per minute.

A rotating abrasive wheel is much to be preferred for grinding to a stationary stone, as it will not chatter or dig into the commutator as a stationary stone may. A medium soft stone must be used to prevent the face filling up with copper. Grinding with a wheel should preferably be done in a machine's own bearings at normal speed, as this will compensate for any distortion which may take place in the shaft when running, due to unbalanced armature.

Special machines are available for grinding commutators and may be attached to the brush holder rigging if desired. Light cuts must be taken both to prevent excessive wear on the stone and to prevent springing of the armature shaft which would tend to reproduce high or low spots. If the commutator is badly out of true, the rough cuts should be taken at medium low speeds and the finishing cuts made at normal speed.

The final surface is best finished by means of a hand stone. More care is required in the finishing of a turned than of a ground commutator because of the threading action of the tool. Turning removes the metal from the commutator somewhat quicker than grinding but does not give quite as true a surface and therefore requires considerably more hand finishing.

The cleaning of the whole of the machine is of the greatest importance after turning, grinding, stoning or sanding the commutator. To make sure that no copper dust has got in where it will do harm, a test of the insulation to ground with about 1,000 volts may save future trouble.

Some Causes of Commutator Troubles

High or low bars are usually the result of loosening up of the commutator. Tighten it up and turn or grind till true. Flat spots may be caused by any of the following causes: Sparking, instantaneous overloads or surges, unbalanced armature, difference of hardness of the various bars or strips of mica. A black commutator is caused by too much lubricant or excessive sparking.

Heating may be the result of: Excessive sparking; local short circuits due to brushes off the neutral, too thick brushes, brushes at too flat an angle, brushes not properly spaced, bent brush holder stud or unequal air gaps between armature and poles, too high brush pressure; too high friction quality of brushes; sand under the ends of the brushes. This last condition is usually shown by copper dust on the brushes or holders. Copper dust will also be picked up if too much lubricant is used or too abrasive a quality of brushes. Noisy brushes may be from any of the following causes: Too much friction; rough commutator; dirty commutator; high mica; high or low bars or flat spots on commutator; eccentric commutator; or loose brushes.

Commutator Slotting

The slotting or undercutting of commutators consists of removing the insulation from between the bars of the commutator to a depth of 1/32 or 3/64 of an inch. This leaves only the copper bars in contact with the brushes.

With flush commutators the brushes used must be hard and have considerable abrasive action to cut away the mica as fast as the copper bars wear away in order that the brushes may make good contact with the copper bars. Abrasive brushes mean more wear and thus shorter life for the commutator, as well as heat and the loss of power from the extra friction.

The undercut or slotted commutators, brushes with very little friction and practically no abrasive action may be used saving the above wear and power losses. On an average machine with flush commutator, the brisk friction may amount to as much as 2½% of the total capacity of the machine. To illustrate the cost of this waste power, consider a 100 k. w. generator operating 10 hours per day, 300 days per year. The total power generated in this time, if machine is fully loaded, is 300,000 k. w. hours. The total power lost in brush friction will then be about 2½% of this or 7,500 k. w. h., which if power costs 1c per k. w. h. will mean a loss of $75 per year most of which might have been saved if low friction brushes had been used.

It sometimes falls to the lot of an operating engineer to re-undercut a commutator which has worn or been turned down to the mica, or to slot the commutator of a machine which originally had flush mica between the bars.

There are several machines on the market for this work all of them fairly satisfactory. The usual power outfit consists of a small milling saw which can be conveniently mounted on the machine. There are also numerous hand tools of special type. The commutator slotting file is probably the simplest and easiest to operate. A properly ground tool operated on a lathe tool carriage may be used with success if available. Broken hack saw blades are sometimes used, but require great care in their manipulation to prevent scratching the surface.

After slotting make sure that no thin strips of mica are left flush with the surface of the commutator. It is well to scrape the slot with a V-shaped tool to slightly bevel the edges of the copper bars, and to detect any chips of mica left too high as well as to remove burrs of copper which if left in the slots would likely cause short circuits and serious burning.

After undercutting, the commutator should be polished according to instructions given above to remove any slight scratches and give a high polish, as the brushes to be used with it have little if any polishing action, and are so soft that even minute scratches will cause excessive brush wear.

Lubrication is unnecessary on undercut commutators, as the brushes have very little friction, especially if of the self-lubricating grades, and oil and grease on the commutator would only serve to collect carbon dust in the slots. If oil is likely to creep into the slots from the bearings or to be splashed onto the commutator, the slots, after being thoroughly cleaned may be varnished with good insulating air drying varnish. They can then easily be washed out with gasoline at any time.

Selection of Brushes

In times past the average operator when in need of brush replacements merely ordered "Carbon Brushes" of the size required from his dealer, and accepted what he received without question, placing the blame on the machine or the load or other conditions if commutation were not good. He generally tried to remedy any trouble by increasing the brush pressure to prevent sparking or by lubricating too freely to prevent wear.

It is only within comparatively recent years that the physical and electrical characteristics of carbon brushes have been seriously studied in connection with their commutating behavior under various conditions.

It is too much to expect that every operating or maintenance engineer should go thoroughly into the question of brush characteristics, and their relationship to operating characteristics. Brush manufacturers on the other hand maintain a staff of research engineers who have available all information on these subjects; and by submitting the conditions under which any machine is operating to them, the proper brush for that machine can usually be recommended by them. Often these brush engineers are available without charge to investigate particularly stubborn cases of poor commutation, they will make a thorough analysis of the conditions of operation and will be able to prescribe the type and quality of brush to most nearly satisfy all the conditions.

Below is a list of data which a brush engineer must have to intelligently select the proper brushes for any particular machine.

1. Size of brushes, number of sets of brushes per set.
2. Whether generator, motor or rotary converter.
3. Direct or alternating current. If A. C. number of phases.
4. Whether for commutator or collector rings.
5. If commutator, whether slotted or not, if collector rings, whether of iron, steel, brass or bronze, etc.
6. Voltage of machine.
7. Full load current.
8. Speed in r. p. m.
9. Diameter of commutator or slip rings.
10. Number of main poles.
11. Whether machine has commutating poles.
12. Type of brush holders, and shunt connections.
13. Degree of bevel on end of brush.
14. Width of commutator bars, or number of bars.

Also name, grade number etc. of brushes which have been in satisfactory use, or preferably a sample, and conditions of brush pressure, lubrication, etc., under which they were satisfactory. Or complete data regarding the manner in which samples submitted have been unsatisfactory in operation.

Most brush manufacturers supply free complete data sheets with spaces for the above information to be filled in. If these sheets are used in ordering brushes, one is sure to get a satisfactory brush, provided the machine is in good order otherwise. Brushes should always be ordered in this way, or at least until some definite grade of some manufacturer's brushes has been found to be perfectly satisfactory, when they may be ordered by catalogue or grade number from that manufacturer of that particular machine.

Brush manufacturers usually have lists of the standard sizes and makes of machines, for which they have determined the proper brush. In this case it will be necessary to give only the nameplate data of the machine to receive the correct brushes.
